When amputation has been practised, this author recommends the exhibition of bark, good wine, tonics, &c. in order to promote the good effects of the operation.—(*P.* 154.)

"The facts (says Larrey) which I shall relate in the course of this dissertation will prove, I think, in an incontestable manner, the truth of the principle which I lay down, that *when gangrene is the result of a mechanical cause, and puts the patient's life in danger, amputation ought to be performed without waiting until the disorder has ceased to spread.*

"I have been a witness of the death of several individuals, from too rigorous an adherence to the contrary precept; and, at length, grievously impressed with this loss, I had long ago determined to depart from an axiom which was always considered by me as false. Besides, following the maxim of Celsus, I preferred employing an uncertain remedy, rather than abandon the patient to an inevitable death. *Satius est enim anceps auxilium experiri quàm nullum.*

"I made the first attempt at Toulon, in the year 1796, upon a soldier, who, in consequence of a violent contusion of the foot, was afflicted with a gangrenous ulcer, which soon threw the whole part into a sphacelated state. While the mortification was yet spreading, I resolved to amputate the leg. The success of the operation surpassed my expectations; the stump healed; and in less than forty-five days the patient got quite well. This case served to encourage me.

"During the siege of Alexandria, in Egypt, in 1801, a second case, very analogous to the preceding, occurred in my practice; it happened in a dragoon of the 18th regiment, whose forearm and afterward arm sphacelated, in consequence of a gun-shot wound in the articulation of the left arm. The mortification had extended nearly as high as the shoulder, and the patient's life was in great danger, when I determined to amputate the limb at the shoulder-joint. The disorder was manifestly spreading, and the patient's brain already affected, for he had symptoms of ataxia; the operation, however, arrested the progress of the slough-

ing, and saved his life, so that at the conclusion of the siege of Alexandria he was quite cured.

"After the taking of Ulm, M. Ivan, surgeon to his majesty the emperor, performed in my presence, and at my ambulance established at Elchingen, the amputation of the thigh of a soldier belonging to the 76th regiment of the line, the leg having sphacelated in consequence of a gun-shot injury. The gangrene was not limited, and evidently extending itself; yet the effects of the disorder were destroyed, and the patient was quite cured on our return to Austerlitz.

"A fourth patient, an officer in the same regiment, shot in the ankle at the capture of the same town, was conveyed to my ambulance, in order to be dressed: it was the third day after the accident: the foot was gangrenous, and the leg was swelled, and threatened likewise with mortification. Febrile symptoms had also come on. I hastened to amputate the leg a little above the place of election. The cellular membrane of the stump, of a yellow blackish colour, was already infected with the gangrenous principle (as Larrey terms it). The operation, however, stopped the progress of the mischief; suppuration took place in the stump; some sloughs were detached; the wound assumed a cleaner appearance; and cicatrization was completed on the fifty-second day. The patient could already walk with a wooden leg, when he caught the hospital fever, which was epidemic at Ulm, where he awaited his regiment, and, to my great regret, he was carried off by this disease, after having escaped the former danger.

"After the battles of Austerlitz and Jena (continues Larrey), several of my colleagues, surgeons of the first class, undertook, in consequence of my advice and the examples of success which I had recited to them, the amputation of limbs equally sphacelated, although the mortification was not limited, rather than abandon the patients to a death which appeared inevitable. In general, these practitioners experienced the same success as I did myself."—(*Mém. de Chir. Militaire, t.* 5, *p.* 154—157.)

In Larrey's memoir upon this subject there are some additional facts and arguments in favour of what he endeavours to prove, viz. that in cases of mortification from external injuries, if the patient's life be in danger, amputation ought to be performed, although the sloughing may yet be in a spreading state. I must be content, however, with having stated the particulars already explained; and the reader, desirous of more, must refer to Larrey's own publication. Certainly the facts which he has adduced are highly important; they tend to subvert a doctrine and to prove the error of a practice which have been urged in forcible terms by most of the distinguished surgeons of modern times. The sentiments of Mr. Sharp are rendered questionable; and the truth of the positive assertions of Mr. Pott is yet a matter to be examined. The latter, it is well known, tells us, that he has often seen the experiment made of amputating, while a mortification was spreading, but never knew it answer. Are we to conclude, that all these cases which Pott alludes to, were mortifications from an internal cause? Or are we to suppose, that the operation failed from having been delayed too long? Or must we imagine, that the nature of the human constitution has been changed between the era of Pott and that of Larrey?

It should be remarked, that the practice of amputation, in cases of spreading mortification, has generally had some partisans for many years past; but the weight of authorities has unquestionably been against it and few surgeons in this country have ventured to deviate from the advice of Sharp and Pott. It is curious, however, that Mehee, a writer, who wrote for the express purpose of declaring his disapprobation of the early performance of amputation in gun-shot wounds, should have admitted of only one case in which the operation is proper, namely, *gangrene succeeding the wound made by a cannon-shot.* Here he thinks that amputation ought to be performed on the first appearance of the gangrene, in order to prevent it from spreading up the limb.—(See *Traité des Plaies d'Armes à feu, Paris*, 1799.) It appears that about the year 1809, Mr. A. C. Hutchinson performed with success two amputations in cases of spreading gangrene from gun-shot wounds.—(See *Practical Obs. on Surgery, p.* 72.)

My friend Mr. Lawrence has also successfully amputated at the shoulder joint in a spreading mortification of the arm, the consequence of external violence. "The skin of the amputated limb was greenish and livid; but the cuticle not yet detached. The cellular substance distended with air, and with a discoloured offensive sanies; its appearance was not quite natural where the incision took place; it was yellowish and anasarcous. Small effusions of blood were observed here and there in the course of the nerves; even as high as the amputated part. No coagulation of blood in any of the arteries, even down to the ulnar and digital branches. All the soft parts were discoloured, dark red, and livid, and a frothy, reddish fluid issued on incision." This case had the most favourable termination, and it clearly proves, that the *humid* kind of gangrene which occurs in a healthy subject from severe local injury, which so rapidly affects a whole limb, and reaches the trunk in a few hours, must constitute an exception to the general maxim, that amputation should never be done before a line of separation is established between the dead and living parts. Mr. Lawrence, however, would not be understood as meaning to recommend the practice in all instances of mortification from local injury. He conceives, that a gangrene may arise, in an unsound constitution, from a comparatively slight accident; so that it may be regarded as the result of constitutional disposition rather than of the local cause. Amputation would be hopeless under such circumstances. It is particularly in mortification following very severe injury in a subject otherwise healthy, that Mr. Lawrence believes the operation to be proper.—(See *Medico-Chir. Trans. vol.* 6, *p.* 184.)

He also reports another instance, in which he saw the operation succeed, though the mortification was in a spreading state. I was once consulted in private practice about the propriety of amputating at the shoulder in a spreading mortification of the arm from external violence. The operation was done, and the patient, who without it would certainly have perished in a few hours, lived a fortnight; at one time he had a fair prospect of recovery, and died, not of gangrene of the stump, but in consequence of a large abscess over the scapula.

Among the experienced approvers of Larrey's advice, I must not omit to mention Dr. Hennen, who has repeatedly amputated under the circumstances above pointed out, without waiting for the line of separation; "and (says he) although I certainly was not uniformly successful, I have no reason to imagine that death was occasioned by a departure from the rule so generally laid down by authors."—(*On Military Surgery, p.* 243, *ed.* 2.)

With regard to the early performance of amputation, where the substance of a limb perishes after exposure to cold, I find some difference of sentiment between two very high authorities. Thus Schmucker observes: "The mortification which comes on after a part has been frozen, increases so rapidly if the limb be exposed to warmth, that in the space of twenty four hours its vitality and organization are quite destroyed, and nothing will now avail in restoring its sensibility. Here the speedy performance of amputation is the only means of preservation to be depended upon. In mortification from an internal cause, the case is different.—(See *Vermischte Chirurgische Schriften, b.* 1, *p.* 15, *8vo. Berlin*, 1785.) According to Larrey, however, this species of gangrene at length stops, and a line of separation forms between the dead and healthy parts. If the disorder be superficial, the sloughs are usually thrown off between the ninth and thirteenth days, leaving an ulcer of proportionate extent, that soon heals up. If the whole of the limb be sphacelated, nature cannot of herself effect a cure, or but very rarely, the patient mostly falling a victim to the effects of absorption, when the sloughs are detached, and the mouths of the lymphatics are opened on the occurrence of suppuration. Larrey assures us, that he has seen numerous patients carried off by this cause, while the examples of a spontaneous cure were exceedingly few, and in these the stump was left irregular, and unfit for bearing the pressure of a wooden leg. He agrees, therefore, with the generality of surgeons, that it is in these instances advantageous to amputate the mortified portion of the limb, *but not before the extension of the gangrene has ceased, and the mischief is bounded by an inflammatory line.*—(See *Mém. de Chir. Mil. t.* 3, *p.* 65—72.)

In the article *Amputation*, notice has been taken of a sloughing which commences in the foot, and extends up the leg, and sometimes follows gun-shot injuries of the thigh, which involve the femoral artery: this is a case particularly instanced by Mr. Guthrie, as requiring the very early performance of amputation. Sir Astley Cooper also refers to cases in which the rule was successfully deviated from, of not amputating before limits are set to the spreading of mortification; the instances in question arose from injury of blood-vessels, and other local violence, in patients of a healthy constitution. In such cases, it is admitted by this very experienced surgeon, that the practice should be different from what is usually pursued in mortification from constitutional causes.—(*Surgical Essays, part* 2, *p.* 186.)

[Dr. Physick was the first surgeon who suggested the application of blisters in strips over the sound parts of a limb next to those which are gangrenous, and its success in this country and in Europe is a matter of notoriety. The pyroligneous acid has also been applied topically in cases of mortification, sloughing, and fetid ulcers. In many ulcers it is preferred by Professor Stevens to the nitric acid or yest poultice, and in its antiseptic powers is superior to either of them. The chloride of soda is becoming an article of general use for these purposes, and is of great value.—*Reese.*]

MOXA. The Chinese moxa consists of the tomentum of the leaves of the artemisia latifolia. That which Baron Percy employs is made of the stalk of the great sunflower, soaked in a solution of nitre, and afterward well dried; cotton, however, similarly prepared, completely answers the purpose. Mr. Dunglison, who has translated Larrey's memoir on this subject, and added to it some interesting matter, shows that the moxa has been used in the eastern parts of the world many centuries. The cone or cylinder of moxa is composed of a certain quantity of cotton wool, over which a piece of fine linen is rolled, and fastened at the side by a few stitches. This conical cylinder should be about an inch long, and of a proportionate thickness; the size, however, may be varied according to circumstances.

A porte moxa is intended to fix the cylinder upon the precise spot where the application is to be made. The metallic ring of this instrument is kept from touching the skin by means of three small supports of ebony, which is a bad conductor of caloric. After the extremity of the cone has been set fire to, the combustion is kept up by means of a blow-pipe; however, it should not be too much hastened, but allowed to proceed slowly. The precise spot to which the moxa is to be applied, ought to be first marked with a little ink, and all the surrounding surface covered with a wet rag, that has a hole in the middle, so as to leave the part bare which has been marked. After the top of the moxa has been set on fire, the base of it, held in the porte moxa, must be placed upon the intended part, and the combustion kept up with the blow-pipe, until the whole is consumed. In order to prevent the subsequent inflammation and suppuration from being too considerable, the liquor ammoniæ should be immediately applied to the burnt part.

The diseases in which Baron Larrey has found the moxa efficacious, are amaurosis, and incipient cataract (cases in which he applies it over the course of the facial nerve, just behind the angle of the jaw); deafness and aphonia arising from cold; tic douloureux, and partial paralysis of the muscles of the face; palsy of the lower extremities; phthisis; diseased spine, disease of the hip-joint, &c.

M. Roux, when he visited the London hospitals, had two opportunities afforded him of applying the moxa, in order to convince the rising generation of surgeons in this country of its superior efficacy. The first was in a case of spontaneous paralysis of the deltoid muscle at St. Bartholomew's. The moxa was applied a little below the acromion, and a few days afterward the motion of the arm began to be restored. This, however, was a case which, according to the account of Roux himself, had relapsed after having been cured by other means. I think one of the surgeons of St. Bartholomew's informed me, that notwithstanding the moxa, the relief proved again only temporary. If; however, the moxa had succeeded, a caustic issue, a blister, or the volatile liniment would probably have answered equally well. The second instance in which M. Roux applied the moxa, was a case of white swelling at Guy's Hospital; but the disease and advanced too far to allow any hope of a favourable issue.—(See *Voyage fait à Londres en* 1814, *ou Parallèle de la Chirurgie Anglaise avec la Chirurgie Francaise, p.* 19, 20.) M. Roux flatters himself that "*les chirurgiens Anglois répugneront sans doute moins à l'avenir à faire usage du moxa.*" The truth is, English surgeons, as well as English farriers, knew very well before the arrival of M. Roux what might be done with moxa and the actual cautery. But though the application of fire still prevails in the veterinary art, as a mode of curing diseases, it has long been abandoned as a means of relief in the English practice of surgery; not on the ground of its being always ineffectual, but because equal good has been found to result from measures which are milder, always less terrific, and frequently less painful. In order to convince an English surgeon that moxa and the actual cautery ought to be introduced into practice, M. Roux should prove, that there is at least some particular disease which may in this manner be cured, but which cannot be cured by other means, ordinarily employed in our practice. He should also make us forget that the application of actual fire was once as common in English surgery as in French; but that it had not attractions enough to maintain its ground.

However, that the reader may know the arguments used by the advocates for the practice, I submit to him

the following observations, which are contained in a periodical work. All the world knows that counter-irritation is of great use in the treatment of disease; and almost all the world knows that different forms of counter-irritation produce different effects on the human body. We do not pretend to specify what is the reason of these different effects, simply because we do not know. But while such men as Percy and Larrey, and twenty others of character, speak so highly in favour of the actual cautery, we perhaps are scarcely authorized to say, that the action of the potential cautery can be made to resemble it in all cases. We can easily understand how the actual cautery should fall into disuse, however good a remedy it might be; for, if we ourselves were patients, we should be slow in believing that the pain of the application was not so severe as our fears point out; but the skepticism of the medical man ought to rest on different grounds. We may say, respecting the moxa, that its action may be more easily regulated than that of caustics, so that by the more or less sedulous use of the blow-pipe, we may create a superficial eschar, or a deep suppurating wound. In fact, in all cases where more than a mere irritation of the skin is required, the moxa affords a certainty in its applications possessed by none of the other caustics. Of course it would be improper to compare the moxa with blisters, or with any other counter-irritant, which acts by irritating the skin without destroying it: if we compare it, therefore, with the emetic tartar ointment, issues, setons, and the caustics, properly so called, we shall find that it possesses greater advantages than they do. The first of these is a long time in destroying the cutis, and it is very uncertain in the quantity of its effect: moreover, whether the effect be produced at all, generally depends on the diligence and knowledge of the patient's attendants, and not on the medical man. Hence it is not likely often to be properly applied. Issues and setons produce but little instantaneous effect; their efficacy, therefore, depends on the irritation and discharge daily kept up. Indeed, these also, if they are left to the care of the patient, which they almost always are, soon become inert and useless. The different caustics approach to the moxa in their properties. Their effect is, in some degree, rapidly produced, and a suppurating ulcer is formed; but still, to produce their smallest effect, a longer time is necessary than the surgeon can conveniently stay with his patient; so that, as the operation of the remedy is dependent on time, and that time varies according to the constitution of the patient, the quantity of effect produced can never be calculated upon. It is very different, however, with the moxa. The effect is almost instantaneous, and the surgeon's hand regulates the quantum of action; so that not only is the moxa the most manageable of counter-irritants that destroy the skin, but, as many medical men believe that suddenness of operation forms not a small part of the efficacy of counter-irritants, the moxa stands also pre-eminent on this ground.—(See *Med. Intelligencer, vol.* 3, *p.* 578; *also Larrey, Recueil de Mémoires de Chirurgie, Paris*, 1821; *and particularly Mr. Dunglison's Translation of the first memoir.*)

MURIATIC ACID. Gargles containing this acid are often made use of with advantage in various cases of sore throat, and the disease known by the name of cancrum oris. The following formula is employed at St. Bartholomew's Hospital. ℞. Rosæ rubræ exsiccatæ ʒij. Aquæ fervent is lbj. Infunde per horam dimidiam, dein cola, et adde Acidi muriatici ʒj. Mellis Rosæ ℥ij. Sacchari purificati ʒvj. Misce.

Muriatic acid appears to have been tried in syphilis earlier than the nitric, Dr. Zeller of Vienna having employed it as a successful remedy for this disease ever since the year 1789.—(*Vide Sim. Zeller's Prakt. Bemerk über den vorzügl. Nutzen d. ullerem, bekannt. Badeschwamens, &c. Nebst. einem Anhange v. d. Salzsaüre, &c. Wien.* 1797.)

As a medicine capable of improving the appearance of venereal ulcers, and of restraining for a time the progress of the disease, it was known to Mr. Pearson many years. He says that he was first induced to give this acid in venereal ulcers of the tongue and of the throat, in consequence of the great benefit which he had seen result from its use in examples of cancrum oris: and without viewing it as an antidote for lues venerea, he has frequently availed himself of its useful qualities, when it was desirable to gain a little time previously to the commencement of a mercurial course. —(*Obs. on the Effects of various Articles in the Cure of Lues Venerea*, *p.* 193, *ed.* 2.) From what he saw, however, he never inferred that the sulphuric and muriatic acids could radically cure the venereal disease; and he ascribed the benefit derived from them partly to their salutary effects on the stomach and constitution, and partly to their agency on ulcers of the throat and tongue, as local applications.—(*P.* 117.) When Mr. Pearson made these observations, the fact which has now been so unequivocally demonstrated in the army hospitals, that nearly, if not all, the forms of disease going under the name of syphilis, may be cured without mercury, had not undergone the strict and impartial investigations which have of late years been devoted to the subject.—(See particularly *Obs. on the Treatment of Syphilis, with an account of several cases of that disease in which a cure was effected without the use of mercury, by T. Rose, in Medico-Chir. Trans. vol.* 8, *p.* 349.) If this point be admitted as fully established, the question about the antisyphilitic virtues of various articles of the materia medica requires to be taken up in a very different light, not clouded with a notion that the disease will certainly get worse and worse, if no remedy whatever be exhibited, or that it cannot finally get well of itself. While these doctrines prevailed, the amendment of any syphilitic affection during the use of muriatic or any other acid, was entirely referred to some specific effect supposed to appertain to such medicine. But now the question involves several considerations; first, the actual virtue of the medicine in expediting the cure of the disease; secondly, the changes which might happen if the complaint were left to itself; and thirdly, the benefit sometimes ascribable to the improvement produced in the constitution under particular circumstances, by the discontinuance of mercury. The latter mineral no longer claims the name of a specific for the venereal disease, either in the sense of the only or a completely certain antidote; because nature herself would in time bring most cases to a favourable conclusion: because the cure can be completed by a variety of other medicines noticed in this publication; and lastly, because mercury, though it may be generally the quickest means of cure, is, in particular cases, complicated with much debility and constitutional irritability, the surest medicine to aggravate the complaint and prevent any progress towards a favourable termination. Here it is enough to know (and Mr. Pearson himself acknowledges the fact) that in the circumstances above specified, muriatic acid is a safer medicine than mercury. The dose is from ten to twenty drops, which are to be mixed with a proper quantity of water.

Muriatic acid has sometimes been employed as the active ingredient in injections for the cure of gonorrhœa, in the proportion of eight or ten drops to four ounces of distilled water.

In cases of poison from muriatic acid, the experiments made by Orfila, lead him to consider calcined magnesia and prepared soap the most fit substances for neutralizing such portion of the acid as may not yet be combined with the texture of the œsophagus, stomach, &c. They should be given as soon as possible after the corrosive poison has been swallowed, care being taken to let the patient drink copiously of warm water, milk, broth, or some mucilaginous diluting liquid. When from the symptoms there is reason to believe that inflammation exists in the viscera, or when spasms and convulsions come on, antiphlogistic remedies and antispasmodics are indicated.—(*Traité des Poisons*, *p.* 476, *vol.* 1, *ed.* 2, *Paris*, 1818.) In order to detect the presence of muriatic acid when mixed with wine or other fluids, we are recommended to distil a portion of it from a small retort over a candle into a phial containing a solution of nitrate of silver. The precipitation of muriate of silver, which is soluble in ammonia, but not in nitric acid, will take place if the poison contain muriatic acid.—(*Thomson's Dispensatory*, *p.* 434, *ed.* 2.)

By Morveau, who employed himself in investigating the merits of Dr. Carmichael Smith's mode of destroying infection, the muriatic acid in the new form of gas was alleged to have the very important quality of neutralizing putrid miasmata. The gas is extricated from common salt by means of sulphuric acid

In this way it is often employed in hospitals as a mode of preventing and obviating infection.

The use of muriatic acid as an application to certain cases of sloughing and phagedena, has been explained in the articles *Hospital Gangrene* and *Mortification*.

MYDRI'ASIS. (From μύδαω, to abound in moisture.) A preternal dilatation of the pupil.

N

NÆVUS. (*Congenitæ Notæ; Envies; Muttermahl; Mother-spots, &c.*) A mole, or congenital mark, or excrescence of the skin. Nævi materni signify the little spots, excrescences, or swellings, with which many children are born. Some of them (says Dr. Bateman) are merely superficial or stain-like spots, and appear to consist of a partial thickening of the rete mucosum, sometimes of a yellow or yellowish-brown, sometimes of a bluish, livid, or nearly black colour. To these the term *spilus* has been more particularly appropriated. Others again exhibit various degrees of thickening, elevation, and altered structure of the skin itself, and consist of clusters of enlarged and contorted veins, freely anastomosing, and forming little sacs of blood. These are sometimes spread more or less extensively over the surface, occasionally covering even the whole of an extremity, or one-half of the trunk of the body; and sometimes they are elevated into prominences of various forms and magnitude. Occasionally these marks are nearly of the usual colour of the skin; but most commonly they are of a purplish red colour, of varying degrees of intensity; such as the presence of a considerable collection of blood-vessels situated near the surface, and covered with a thin cuticle, naturally occasions.—(See *Bateman's Practical Synopsis of Cutaneous Diseases, p. 324, ed. 4.*) When a nævus is of a dark red colour, its intensity is generally augmented by every thing which tends to accelerate the circulation of the blood. Fits of anger, hot weather, fevers, and the period of menstruation in particular, are observed to be attended with an increased turgescence and discolouration of the part affected. Indeed, the excrescence sometimes bursts, and pours out a dangerous quantity of blood, and in females it has been known to become the seat of a regular menstrual discharge.—(*Boyer, Traité des Maladies Chir. t. 2, p. 277; and John Bell's Principles, Discourse 9.*) Some nævi, especially those usually called *moles*, frequently have long, irregular hairs growing upon them; while the surface of others is streaked, and even granulated. Such as appear in the form of a mere red, purplish stain, have been absurdly supposed to arise from a desire for claret, or some other wine of that colour, entertained by the mother of the patient during her pregnancy. The granulated nævi have been compared with raspberries, strawberries, mulberries, &c. for which the mother's longing is ascribed by the vulgar as a cause. The truth is, however, that this doctrine, imputing the origin of nævi to fancies of the mother, is neither consistent with experience nor sound physiology. The causes (as Callisen observes) "potius autem in evolutione primorum flaminum, a naturæ solita via aberrante, uti in aliis rebus monstrosis quærendæ erunt."—(*Syst. Chir. Hodiernæ, vol. 2, p. 201.*)

From what has been said, then, it appears that certain nævi are merely cutaneous spots of a red violet or purplish colour of greater or less extent, and with scarcely any perceptible elevation. They are an organic malformation of the skin, the natural texture of which does not exist, but a plexus of vessels is substituted for it, not endued with the natural sensibility of the cutis itself. These nævi generally continue stationary during life, and may be regarded rather as a deformity than a disease.—(*Lassus, Pathologie Chir. tom. 1, p. 477.*) Other nævi are either of the same nature as the disease, well known by the name of the aneurism by anastomosis, or bear a considerable resemblance to it. They are sometimes of great size; and their shape is subject to much variety. They are soft and indolent, and of a violet or dark red colour. The skin which covers them is very thin, and when they are opened their structure is like that of a spleen whose blood-vessels are varicose. Some are covered with a delicate white skin, and do not increase with age. Others are more disposed to grow large. These tumours frequently occur in the skin of the face, and in other parts of the integuments on the inside of the labia pudendi and cheeks, and in the substance of the upper and lower lip, where they sometimes form a kind of elongation attended with great disfigurement. Nævi of this kind, so situated in new-born infants, may produce a serious obstacle to the action of sucking. M. A. Severinus has particularly described them under the appellation of "tuberculum atro-cruentum labii inferioris."—(*De Abscessuum Natura, cap. 29, p. 803.*)

The nævi which form in the subcutaneous cellular substance, and were named by Petit "loupes variqueuses" (*Œuvres Posthumes, tom. 1, p. 276*), are also of the same nature as the aneurism by anastomosis. In time they attain a very large size. Mr. Latta says, he once saw in a child two years old a tumour of this kind, weighing fourteen ounces, which at the time of birth was only equal in size to a large bean. During the first year it did not enlarge much; but it afterward grew rapidly to the size already specified.—(*System of Surgery, vol. 2, chap. 22.*) Lassus has even seen a tumour of this description as large as a man's head.—(*Pathologie Chir. tom. 1, p. 479.*) Having treated particularly of the "aneurism by anastomosis," in another place (see *Aneurism*), I shall merely repeat the necessity there is for cutting every particle of the disease away, every portion of the congeries of vessels and cells of which it consists, whenever it is meddled with at all. Puncturing the swelling, or the partial removal of it, has cost many persons their lives by hemorrhage, as the records of surgery fully prove.—(*Petit, Traité des Maladies Chir. t. 1; Lassus, Pathologie Chir. t. 1. p. 484, &c.*)

Although the original causes of nævi are buried in obscurity, experience proves that whatever produces irritation in the part affected, or an increased determination of blood to it, has generally the effect of accelerating the growth and enlargement of the swelling. Thus, a trifling bruise, or a tight hat, will sometimes excite a mere stain-like speck, or a minute livid tubercle, into that diseased action which occasions its growth.—(*Bateman's Pract. Synopsis, &c. p. 327, ed. 3.*)

When these marks or swellings are superficial, without any disposition to enlarge or spread, and their trivial elevation does not expose them to accidental rupture, there appears to be no good reason for interfering with them. Indeed, they could only be destroyed with caustic, the knife, or a ligature, and these severe means would leave scars, accompanied with nearly the same degree of disfigurement.

But, as a valuable writer observes, when nævi evince a tendency to enlarge, or are very prominent excrescences, and either troublesome from their situation, or liable to be ruptured, either their growth must be repressed by sedative applications, or the whole congeries of vessels extirpated with the knife. Mr. Abernethy has proposed the application of cold washes, and the pressure of a bandage. This practice was found by him in several instances to have the desired effect of checking the growth of the tumours, which afterward shrunk, and became no longer objects of any consequence.—(*Surgical Works, vol. 2, p. 224.*) Boyer also knew of a case in which a nævus of the upper lip was cured by the mother pressing the part with her finger unremittingly for several hours at a time, and the use of alum wash.—(*Traité des Maladies Chir. t. 2, p. 269.*) Boyer, however, is not generally an advocate for this mode of treatment; and Dr. Bateman expressly states, that, in the majority of cases, pressure

is the source of great irritation to these maculæ, and cannot be employed.—(*P.* 329.)

Modern experience tends to prove, that superficial nævi may sometimes be successfully treated by plans calculated to produce an effusion of lymph in their structure, and perhaps an obliteration of their vessels. It must be, I presume, on this principle that some nævi have yielded to the effects produced by the insertion of vaccine matter into several points of the tumour; and it is not impossible that the same result might follow the injection of a stimulating lotion into the texture of the part affected.

For all those examples, which partake of the nature of aneurism by anastomosis, and are disposed to grow, the best general mode of cure is extirpation. The exceptions to this plan are certain examples, in which the tumour seems to derive its main supply of blood from some large artery, the trunk of which will admit of being tied. The prudence of extirpating the disease, ere it extend too far, and the necessity of taking away every particle of the disease, has been already explained; this is what was advised by F. Hildanus (*Cent.* 5, *Obs.* 46); what was strongly urged by the celebrated Petit (*Œuvres Posthumes*, *t.* 1); what was recommended in still more animated terms by Mr. John Bell (*Principles of Surgery*, *Discourse* 9); and it is what is particularly insisted upon in another part of this Dictionary.—(See *Aneurism.*)

The hemorrhage from the excision of some nævi, however, is so profuse, and the difficulty of cutting all the disease so great, that my friends Mr. White, of the Westminster Hospital, and Mr. Lawrence, of St. Bartholomew's, have sometimes preferred the plan of extirpating nævi by the introduction of a double ligature through their substance, and then tying each half of the swelling with sufficient tightness to make it slough. —(See *Med. Chir. Trans. vol.* 13.) This treatment certainly seems safer than excision, when the tumour is of considerable size.

Mere thickenings, and discolourations of the rete mucosum, have sometimes been removed by a mixture of spirit and the liquor potassæ.—(*Bateman*, *p.* 330.)

I was lately consulted by Mr. Smith of Tottenham Court, about a superficial nævus on the neck of a female infant: I recommended it to be frequently touched with diluted nitric acid, by which means it has been gradually reduced to one-half of its original size, without ulceration; and I have no doubt that perseverance in the plan will complete the cure.

Formerly, caustic was much in vogue for the removal of nævi; but unless its action extend deeply enough to destroy every part of the disease, it may cause a dangerous and useless degree of irritation, copious hemorrhages, and a sudden and fatal enlargement of the tumour. It cannot be denied, however, that the old surgeons had success with their caustics, where the nævi were altogether superficial. Thus, in speaking of caustic remedies, Callisen observes: "inter quæ eximio cum successu adhibetur sapo cum æquali parte calcis viva subtilissime commixtus, nævo per emplastrum perforatum admovendus, et alio emplastro imposito firmandus; hoc remedio eschara inuritur qua soluta, cicatrix alba remanere solet."—(*Syst. Chirurgiæ Hodiernæ*, *vol.* 2, *p.* 202.)

Mr. Wardrop, having seen cases in which nævi were cured by accidental attacks of ulceration and sloughing, which destroyed a great part of the tumour, and brought on such inflammation as consolidated the rest, was led to imitate this process by adopting the ancient practice of applying the kali purum. He found the method answer in several instances; but it is evidently only calculated for nævi below a certain size.

[Vaccination has been proposed as a remedy for the removal of those small *nævi materni*, when found on the face or neck, and, so far as the experiments have been reported, the result is favourable to the practice. Dr. Pendleton of this city informs me, that he has lately tried it in a case, in a new-born infant, the nævus being situated in the face. He introduced the vaccine virus at two opposite points on the margin of the tumour; the infection was communicated, and had the two pustules met, the deformity would have been entirely removed. The only portion of the disease left is that between the two cicatrices left by the pustules, and is very inconsiderable. It surely merits a trial in every such case; and if three or more points of infection could be obtained, so as to envelope the tumour, it will doubtless succeed, and is preferable to excision by the knife or ligature.

When these nævi are obviously belonging to the class of aneurism by anastomosis, situated on the head, if they be very prominent excrescences, and evince a tendency to grow, as they often do with great rapidity, their extirpation becomes indispensable. And in such cases the method practised by Dr. Physick is, to run round the tumour with a scalpel, cutting down to the pericranium, and then tying the arteries separately. Lint is then interposed to prevent union by the first intention. The circulation being thus cut off entirely, the case is readily disposed of by the other methods named by Mr. Cooper. This method has been very successful in this country in the hands of Drs. Mott and Jamieson, as well as Dr. Physick, and is greatly to be preferred to the cruel and equivocal plan of Mr. White, by the ligature.—*Reese.*]

NECROSIS. (From νεκρόω, to destroy.) This word, the strict meaning of which is only mortification, is, by the general consent of surgeons, confined to this affection of the bones. It was first used in this particular sense by the celebrated M. Louis, who restricted its application, however, to examples in which the whole thickness of a bone was destroyed.—(See *Mém. de l'Acad. Royale de Chirurgie*, *t.* 5, *4to.*) By the ancients, the death of parts of bones was not distinguished from caries. However, necrosis and caries are essentially different; for, in the first, the affected part of the bone is deprived of the vital principle; but this is not the case when it is simply carious. Caries is very analogous to ulceration, while necrosis closely resembles mortification of the soft parts.

Between caries and necrosis, says Weidmann, there is all that difference which exists between ulcers and gangrene, or sphacelus of the soft parts. In caries, the nutrition of the bone is only impaired, and an irregular action disunites the elements of the bony structure, which consequently sustains a loss of substance; but every remaining part of it is yet alive. In necrosis, on the contrary, the vitality and nutritive functions cease altogether in a certain portion of the bone, the separation of which then becomes indispensable.—(*De Necrosi Ossium*, *p.* 7.)

I have mentioned that M. Louis confined the term necrosis to cases in which the whole thickness of a bone perished: but Weidmann judiciously criticises this limitation of the word, and maintains that the nature of the disorder is the same, whether it affect a single scale, the whole, or a mere point of the bone. He also objects to the definition of necrosis proposed by Chopart (*Dissert. de Necrosi Ossium*, *Parie*, 1765), and adopted by David.—(*Obs. sur une Maladie connue sous le nom de Nécrose*, *Paris*, 1782.) These two authors have defined necrosis to be a disorder in which a portion of bone perishes, and turns dry, in order to be soon separated from the living parts, and replaced by a new bony substance, which is to perform its functions. But, as Weidmann observes, it may happen that a piece of bone, which dies and separates, may not be replaced by any new formation of bone, though the disease is of the same character, and merely varies in some modifications. He therefore argues, and every rational surgeon will agree with him, that a true necrosis must always be said to exist, whenever a dead portion of bone has either separated, or is about to separate. "*Vera demum necrosis semper est, si aliquod ossis tomentum, in quo vis vitæ, extincta est, abscessit, vel proxime abscessurum. est*"—(*B.* 7.)

The tibia, femur, lower jaw, clavicle, humerus, fibula, radius, and ulna, are the bones most frequently affected with necrosis. Excepting the lower jaw and scapula, the process of regeneration has only been noticed in the cylindrical bones. From 12 to 18 years of age is the time of life most subject to necrosis. Necrosis of the lower jaw, however, seldom occurs before the age of 30.

No climate, age, sex, mode of life, nor condition (says Weidmann), is exempt from this disorder Childhood and puberty, however, are the periods most liable to it. The same thing may be said of persons who labour hard, and are much exposed to external injuries. Every bone of the human body is subject to necrosis; but those which are superficial, and enter into the formation of the extremities, are more frequently affected than others whose situation is deeper. Necrosis less commonly attacks the spongy substance of the bones, because this being endued with a higher degree of vascularity and life, suppuration is most apt to occur. Necrosis, on the contrary, is oftener seen in the compact substance, where the vital principle is less energetic, and more readily extinguished. As a modern writer has remarked, a very slight injury will frequently occasion an extensive exfoliation from the surface of the cylinder of a long bone; but a musket-ball may pass through the cellular structure of an epiphysis, or lodge in its substance, without giving rise to necrosis, suppurative inflammation being much more likely to occur than the latter affection.—(*Bell on Diseases of the Bones, &c. p.* 49.) Lastly, necrosis may affect the long bones or the broad, the large or small, and even those of the very least size; since it is well known that the ossicula of the ear may be destroyed by necrosis, and separate. I have seen this happen in two instances, and the fact is recorded by several writers —(See *Astruc de Morbis Venereis, lib.* 4, *cap.* 1. *Henri, Journal de Médecine, t.* 15, *p.* 363.)

Though necrosis mostly attacks the cylindrical bones, the flat ones are not exempt from the disease. Pott makes mention of a parietal bone, the whole of which was detached, and of an os frontis, the greatest part of which came away. In a thesis on necrosis, written in 1776, may be found the case of a young man, a very large part of whose scapula perished and separated. Chopart, who relates the case, mentions, that he saw the patient quite recovered, and felt a new triangular moveable bone, firmly supporting the clavicle, but smaller and flatter than natural, and without any spinous process. The same has happened to the lower jaw, as may be seen by referring to the *Ephemerides Nat. Cur.* and *Mém. de l'Acad. de Chirurgie.* In the fifth volume of the latter work, is an account of a woman who applied to be relieved of some venereal complaints. From the beginning of the treatment, the bone was discovered to be loose just under the gums, and seemed shortly afterward to move backwards and forwards with a tooth. Mr. Guernery took hold of the tooth with a key-instrument, and found it firmly inserted in the moveable jaw; he made with caution the necessary manœuvres for extracting the portion of bone; but was greatly surprised on finding what an extensive part yielded to his very moderate efforts. It was the whole of the lower jaw, above its right angle, from its division into the coronoid and condyloid processes to the space between the first and second of the front grinders of the left side. On the right, there only remained the condyle in the articular cavity of the temporal bone. This destruction left a considerable empty space, from which great deformity was apprehended, in consequence of the unsupported soft parts falling down. The woman, however, got well in two months, and had the most perfect use of a new jaw. A similar fact is recorded in the *Journal de Médecine*, 1791.

When the body of a cylindrical bone, or the middle portion of a flat bone, is destroyed by necrosis, their extremities, which are of a cellular texture, generally continue unaffected, so that, for example, in the cylindrical bones, the articular ends are always formed of portions of the original bone, which are engrafted as it were on the new production. There are, however, a few bad cases, in which the necrosis does not altogether spare the heads of the bones, and the disease communicates with the joint. These examples are very uncommon, and are attended with considerable danger to the limb: indeed, they generally require amputation.—(See *Boyer, Traité des Mal. Chir. t.* 3, *p.* 442.) Mr. Brodie has known an instance, in which, without any obvious cause, a large portion of the head of the tibia died and exfoliated, and the destruction of the knee-joint was the consequence.—(*Pathol. and Surg. Obs. on the Joints*, *p.* 269.)

It is not, therefore, correct to assert absolutely, as Mr. C. Bell has done, "that the extremities of bone are not subject to necrosis."—(*Surg. Obs. p.* 321.) It would be more accurate to say, that these parts are not frequently attacked.

Besides the differences arising from the particular bones affected, necrosis also varies according as the portion of bone attacked happens to be thin and of little extent, or large and of considerable thickness. The disease is *simple* when it is confined to one bone, and the patient is in other respects healthy; *compound*, when several different parts of the same bone, or several distinct bones, are affected at the same time; when the health is bad; and other parts of the body are also diseased. It should also be known, because the information is of practical importance in the treatment, that necrosis has three different stages or periods. In the first, the bone affected perishes; in the second, the process of exfoliation or separation of the dead bone from the living, is going on; and in the third, the separation is completed.—(See *Weidmann, p.* 8.)

Necrosis is divided by some writers into the *traumatic* and *idiopathic*. In the latter, the exfoliations are generally more extensive and deep than in the former, and frequently comprehend the whole thickness of a bone. The idiopathic is also that which is mostly met with in the flat bones.—(See *Bell on Diseases of the Bones, p.* 50.)

The causes of necrosis are not essentially different from those which produce ulcers and gangrene of the soft parts. As, however, the vitality of the bones is weaker, we may infer, that necrosis may be occasioned in them by causes which are less numerous and intense, and such as would only give rise to suppuration in the soft parts. Every thing, whether in the periosteum or the substance of the bone itself, that tends to interrupt the nutrition of the bone, must be regarded as conducive to the origin of necrosis. It is observed, however, that when the mischief in the periosteum, medulla, or substance of the bone is of trivial extent, the consequence is merely an abscess. Some of the causes of necrosis are *external*, while others are *internal* or constitutional. Sometimes the life of the bone is instantaneously destroyed by them; but in other instances, the bone is first stimulated and enlarged, so that its death is preceded by true inflammation.

The external causes which injure the periosteum and medullary structure, and thus produce necrosis, are wounds, contusions, pressure, fractures, comminutions, acrid substances, caustics, and extreme degrees of heat or cold.

When the periosteum in consequence of an external cause inflames and sloughs, or is at once deprived of its vitality, as it may be by the action of caustic, fire, or intense cold, the vessels which conveyed nourishment to the bone are destroyed, and the death and exfoliation of the denuded portion of the bone are inevitable. But if the detachment of the periosteum is of little extent, the patient young and healthy, and the treatment calculated to prevent inflammation and preserve uninjured the vessels distributed to the bone, hopes may be entertained that no part of the bone will die, but that granulations will very soon arise from its surface, being adherent to it as the periosteum was, and that they will grow to and cicatrize with the surrounding parts. Weidmann has explained, that this fact of bones not always exfoliating when deprived of the periosteum, which is of great practical importance in the treatment of wounds, was inculcated by Felix Wurtz, Cæsar Magatus, and Bellosie, at a time when the contrary opinion prevailed. Weidmann also adverts to his own experience and to the experiments of Tenon, in farther proof of the preceding fact.—(*Mém. de l'Acad. des Sciences*, 1758, *p.* 372.)

On the other hand, when the detached piece of the periosteum is extensive; when the bone itself is contused; or when it has been long exposed to the air, the effect of which is to dry up the few vessels which belong to it: when the inflammation is violent and extensive; when the patient is old, decrepit, or of bad constitution; and more especially, when improper appli-

cations are used, as was almost always the case in former times, necrosis cannot be avoided.

An internal necrosis, affecting the spongy texture of bones, generally arises from constitutional causes, though sometimes an external cause, which seems to affect only the surface of a bone, extends its action to the interior, so as to destroy the medullary membrane, and produce an internal necrosis.

In external injuries of the head, where the pericranium is lacerated, contused, or otherwise hurt, or where the outer table, or the diploe of the skull, is injured, the inflammation frequently extends to the inner table, and the dura mater becomes detached. Hence, a collection of matter forms, which may occasion many bad symptoms, and even death itself: or, if the patient survive, exfoliation of part of both tables of the skull is the consequence.—(See *Pott's Chir. Works, Lond.* 1779, *vol.* 1, *p.* 32.)

The same thing may occur in other bones, as well as those of the cranium. Bromfield had an opportunity of seeing a necrosis of the spongy substance of the upper and internal part of the tibia, brought on by the improper mode in which an issue was dressed. In order to keep the peas from slipping out of their places, a compress with a shilling in it, and a tight bandage, were applied; but the part was attacked with excruciating pain, and the spongy texture of the tibia in the vicinity became affected with necrosis.—(*Chir. Observations and Cases, vol.* 2, *p.* 9.)

This circumstance, as Weidmann observes, ought not to surprise us: as numerous vessels quit the periosteum to descend into the substance of the bone, to ramify on the medullary cells themselves, and freely anastomose there, it cannot be difficult to conceive how inflammation, which is at first confined to the outside of the bone, may (through the medium of the vessels which serve as conductors to it) penetrate more deeply, and extend its ravages in every direction.

But necrosis may proceed from another description of causes which are of a constitutional nature. In fevers of bad type, in the small-pox, and in the measles, experience has fully proved that the bones are sometimes attacked with necrosis. Scrofula, lues venerea, and the scurvy are also diseases, which, according to the testimony of all surgical writers, frequently produce such mischief in the bones as terminates in necrosis. It is likewise well ascertained, that mercury may itself give rise to the disorder, especially in the lower jaw-bone.—(See *Mém de l'Acad. de Chir. t.* 5, *p.* 356, 4*to.*)

This happens either in consequence of mercury having been introduced too quickly into the system, or because the patient exposes himself to cold, or deviates in some other respect from a proper regimen. Certain necroses of the lower jaw, however, appear also to have been caused by blows, and the application of acrid substances to carious teeth. But, says Weidmann, "I feel it incumbent upon me particularly to declare, that the irrational treatment pursued by the ancient practitioners, who neither understood the nature of the bones, nor the differences of their diseases, and which treatment is too confidently adopted in our own days, had frequently the effect of killing these parts, by attacking with spirituous, acrid, or caustic remedies, or even with the knife, diseases which required the mildest applications, and to be left in a great measure to nature. The old surgeons were afraid of laying on the exposed injured surface of a bone unctuous emollient dressings, and yet, for what reason I know not, they subjected the part to the action of spirituous, acrid, drying applications. As for myself, I deem it proved by infallible and frequently repeated trials, not only that an exposed injured bone may be dressed with a mild ointment without any ill consequences, but even with the greatest advantage. Why should that which is beneficial to the soft parts be so prejudicial to the bones? In ulcers of the soft parts, indeed, the employment of the remedy which I recommend is less important, because these parts are naturally humid, and there is no risk of their becoming dry. But with regard to the bones, whose dry texture is only penetrated by few vessels, which may easily be destroyed if they be suffered to become quite dry, it is absolutely necessary to use an emollient ointment, as a dressing well calculated to defend these vessels, which are the support of life, and preserve them from the bad effects of exposure to the air. Therefore, observes Weidmann, if a surgeon would avoid producing a necrosis himself, and not neglect any means that tend to prevent such disorder, *he should make it a rule never to apply any thing acrid to exposed bones, but on the contrary to defend them with a dressing of some unirritating ointment.*"—(*De Necrosi Ossium, p.* 11.)

It was formerly supposed, that purulent matter, collected near a bone, might in time become acrimonious, corrode it, and produce necrosis. Hence, it was a rule to open such an abscess as soon as its existence was known. But Weidmann questions whether there was any real necessity for this practice. No doubt, says he, the preceding erroneous opinion arose from the circumstance of the bones being often found bare, carious, or even affected with necrosis, when abscesses were near them; but things happened thus, because the inflammation which caused the suppuration had also extended its effects to the periosteum and bone. He affirms, that he has witnessed ulcers, in which the surface of bones, bare and uncovered by the periosteum, lay bathed in pus for a very considerable time; yet, being dressed with a mild ointment, they continued entire, granulations grew from them, and cicatrization followed. He had also in his possession portions of bones affected with necrosis, which had lain for years in pus; still their surface was smooth, and presented no marks of erosion. If, then, these pieces of bone underwent no alteration, how much less likely to do so are bones which are endued with life!

But, though Weidmann wisely rejects the doctrine of pus being capable of destroying the periosteum and bones by any corrosive qualities, he acknowledges his belief, that the matter of an abscess may by its quantity compress and inflame the adjacent parts, and occasion their removal by the absorbents. While the periosteum intervenes between an abscess and the bone, he does not see how the latter can be hurt by the pus; but when the abscess is copious and lodged between that membrane and the bone, the vessels passing from the former will be destroyed, and either caries or necrosis ensue.

The inflammation, arising from the causes which excite necrosis, may be either *acute* or *chronic*. It is chronic when it begins and passes through its different stages slowly, and when the mildness of the symptoms may lead us to mistake the nature of the case. This sort of inflammation chiefly happens in debilitated constitutions, in which the necrosis only affects the external part of a bone, and originates from some chronic cause, such as scrofula, lues venerea, and the scurvy. But when necrosis attacks the interior, and the disease occurs in a strong, irritable, plethoric subject, inflammation is immediately kindled, attended with the most acute symptoms, severe pain, considerable fever, restlessness, delirium, &c. Chronic inflammation is more supportable; but its duration is longer: acute inflammation is more afflicting, but sooner comes to a crisis.

The part in which a necrosis is situated, is affected with swelling. What has been observed respecting the inflammation is also applicable to this tumour, which most frequently forms gradually, but sometimes with great rapidity. In the first case, the accompanying pain is dull and inconsiderable; in the second, it is violent. The swelling has not, like that of abscesses, an elevated apex. On the contrary, it is so widely diffused, that the limits which circumscribe it can hardly be distinguished.

This diffusion of the swelling is the greater in proportion as the diseased bone is more deeply buried in soft parts: it may extend over the whole morbid bone, or even over the whole limb.

The swelling comes on at the very beginning of the disorder, and continues to increase until the matter which it contains finds its way out, when the evacuation is followed by a partial subsidence of the tumour. The swelling is sometimes also combined with œdema, especially in persons whose constitutions have been impaired by the severity of the disease, the violence of the sufferings, and the long and profuse discharge.

When the inflammation is acute, purulent matter of good quality soon collects in the vicinity of the necrosis. In the contrary case, the pus forms slowly, and is thinner and less healthy.

The abscess which accompanies a necrosis naturally soon bursts, when it arises from intense inflammation, and is situated near the skin, which is itself inflamed. But when the bone is surrounded by a

great thickness of soft parts, and the inflammation is chronic, the quantity of matter daily increases, the cavity which it occupies becomes larger and larger, and considerable pressure is made by the abscess on every side. The bones and tendons resist for a long while the progress of the matter; but the cellular substance yields, and different sinuses form, which sometimes run to a vast distance from the main collection of matter, especially when the abscess lies under an aponeurosis.

It was supposed, a few years ago, that in cases of necrosis the matter was invariably sanious, acrid, and fetid. But the celebrated Weidmann exposed the error of this opinion. He had often seen abscesses and ulcers arising from necrosis discharge a whitish, inodorous, thick pus, absolutely devoid of any bad quality whatsoever. He had particularly seen this happen in patients whose necroses proceeded from an external cause, or an internal one of a slight nature, and whose health was generally good.—(*De Necrosi Ossium, p.* 16.) If, says the same excellent writer, we sometimes find in practice the suppuration dark and fetid, we must not ascribe it to the affection of the bone; but to the weakness and bad state of the patient's health. Under the same circumstances common sores of the soft parts would also emit a discharge of bad quality.

After the ulcerated openings have emitted for some time a profuse discharge, the sinuses, if considerable, receive the appellation of fistulæ, on account of their edges putting on a callous appearance, throwing out fungous granulations, and there being impediments to cicatrization. These impediments are caused by the dead portions of bone, which, whether loose or adherent, act as extraneous bodies in hindering the sores from healing. In some instances, also, the ulcers will not heal, though the dead bone has come away, because they run to a great depth, and such a quantity of pus is secreted from every point of their surface as prevents all contact, and the adhesions which would result from it.

The fistulæ vary in number; but they are fewer in proportion as the disease is slighter. In an extensive necrosis several of these openings are seen, either near together or separated by considerable spaces; and when the necrosis affects every side of the bone, the fistulæ in the integuments occur on every side of the limb.

Besides the inflammatory fever which attends the beginning of every severe case of necrosis, which is sometimes accompanied with exceedingly violent symptoms, and which usually abates when matter is formed, the patient is subject to another fever of a slow, hectic type. This takes place in the decline of the disease, is the effect of the long-continued profuse suppuration, gradually reduces the patient, and at length brings him to the grave, unless the timely removal of the sequestrum be effected either by nature or art.

Let us next endeavour to trace the signs by which we may not only ascertain the presence of the disease, but its modifications.

In the first place, we should make ourselves acquainted with every thing which may have predisposed to the disorder; as, for instance, what accidental circumstances have occurred, and what symptoms followed them. We should also inquire into any previous treatment which may have been adopted; for, as Weidmann truly remarks, injudicious remedies have caused many a necrosis that would not have occurred at all if the case had been properly treated or confided to nature.

The kind of inflammation with which the disease commences may afford grounds for suspecting that necrosis will happen: it is generally slow and deeply seated, passing through its stages tardily, and the attendant symptoms are severe. The skin retains its natural colour a long while; but at length exhibits a reddish or livid discoloration. The matter does not reach the skin till a considerable time has elapsed, and when the abscess bursts, the inflammatory symptoms are still slow in subsiding. When the inflammation is acute, the patient suffers intolerable pain a long time.

There are also other symptoms of a necrosis; viz. the swelling which accompanies the inflammation is situated upon a bone, or rather the bone is included in the tumour; the swelling is at the same time very diffused; and the suppuration lies deeply, and can only be felt in an obscure way.

The ulcers, beneath which a necrosis is situated, discharge a large quantity of matter, and their edges are bent inwards. The granulations are either yellowish and pale, or else of an intense red colour; they are also irregular, and generally not very tender, though sometimes extremely painful, and on being slightly touched they bleed.

It has been already noticed, that some years ago the discharge from the sores which attend necrosis was described as being always thin, fetid, and sanious; and such qualities of the matter were regarded as a symptom of the disease of the bone. But as that excellent practical writer Weidmann has explained, it is a symptom undeserving of confidence. In necrosis, the pus is often thick, white, and inodorous; while other ulcers, unattended with diseased bone, sometimes discharge thin fetid matter. Weidmann, at the same time, does not mean to assert, that in necrosis the sores never emit unhealthy pus; but he firmly believes, that such discharge is not always the result of a disease of the bone. As far as he could judge, the suppuration from ulcers situated over diseased bones, continues white and laudable as long as the patient's general health is good; but that it deviates from these properties in proportion as the health becomes impaired.

Neither is the black colour imparted to the dressings of ulcers a circumstance which necessarily indicates the existence of necrosis; for it may occur when the bone is sound, and may not happen when the bone is affected.

None of the preceding symptoms convey such information as leaves no doubt of the positive existence of necrosis. The touch is the only thing which can give us this knowledge, when the bone is not too deeply situated, and the sinuses not tortuous, nor obstructed with fungous growths.

When the openings of the ulcers are considerable, the finger may be introduced. If in this way the bone can be felt to be extensively uncovered by the periosteum, the surgeon may conclude that all such portion of the bone has perished. He may be still more certain of the fact when he finds the edges of the denuded bone unequal and rough.

The examinations made directly with the finger give the most correct and exact information of the state of the bone; but the orifices of the sores are sometimes so small that the finger cannot be introduced without causing great pain. A probe must then be used for the purpose of ascertaining the extent of the denudation of the bone; whether its edges are rough; whether the dead portion is loose, and likely to separate soon.

Sometimes the dead fragment of bone protrudes from the ulcer, or is visible on separating its edges. When it is black, there cannot be a doubt of its being actually dead; but on the other hand, when its whiteness is increased, the diagnosis is difficult, because bones being naturally white, much experience is necessary to be able to judge whether they are so in excess.

It merits attention, also, that the black colour of the bone is not owing to the necrosis itself, but seems rather to depend upon the fragment having been exposed to the air. In fact, dead pieces of bone with which the air comes into contact turn black, while those which are covered with matter retain their whiteness. The cylindrical portion of a humerus, which was almost totally affected with necrosis, was universally black at the part which protruded through the flesh; but the rest, which lay under the integuments, was white.—(*Weidmann de Necrosi Ossium, p.* 19, *et tab.* 9, *fig.* 1.)

When the early symptoms of the disease are mild, the surgeon may infer that it is only a superficial portion of the bone which is about to be separated. But this judgment will be more certain if confirmed by examination with the finger or probe; or if the swelling which occurred in the beginning has not spread beyond the affected point, and if the pain affects only the outer part of the bone. In this sort of case there is also great probability that the dead bone will be separated within a moderate time.

It is also of importance to ascertain the existence of an internal necrosis, and to learn whether it is situated in the spongy substance, or in the internal parietes of the canal of the bone; whether it affects only a part or extends to the whole body of the bone. When there is an internal necrosis, says Weidmann, the disease is generally more aggravated, and of longer duration; and in the first stage the patient is affected with severe symptoms, intolerable pain, loss of rest, a great

deal of fever, profuse perspirations, and such disorder of the system as may prove fatal, unless the patient be young and strong. The hard swelling which was observable at the commencement of the disease, increases but slowly, and extends very gradually over the circumference of the limb, while the skin yet remains free from redness and tension. *If the part be somewhat roughly handled, the pain which is fixed in the bone is not rendered more acute, as would happen were the case an external inflammation.* In this suffering condition the patient continues a good while before the formation of matter brings a degree of relief. When the matter is formed, it spreads through the adjacent cellular substance, among the muscles and other parts, and the abscess generally bursts, after a considerable time, by several openings very distant from the main collection of matter, as also remote from each other, sometimes in diametrically opposite situations. The evacuation of the matter, however, does not produce any material subsidence of the swelling. The pus is of good quality, and issues in large quantities from the ulcerated apertures, *the quantity, however, not being increased when pressure is made.* If some of the openings heal, others are formed; but, in general, the edges become callous, and they lose all disposition to cicatrize. When the case presents the foregoing circumstances, and the weakened limb can neither bear the action of the muscles nor the weight of the body, and by either of these causes its shape becomes altered, the surgeon may conclude that the disease is an internal necrosis. But in order to avoid mistake, he should introduce into the sinuses a probe, which, passing through the openings in the subjacent bone, will touch the dead piece which it contains, and which will sometimes be even distinguished to be loose and moveable. *The extent of the sequestrum must be judged of by the extent of the swelling, and the distances between the apertures in the bony shell which includes the sequestrum.*

The surgeon should also endeavour to ascertain with the probe whether there is only a single sequestrum or several. When there are several, they may be felt with the probe in different places, down to which this instrument is passed, and the removal of one or two of the fragments is not followed by a cure. It ought to be remembered, however, that the same fragment may be touched by the probe in several different places when it is very extensive. If there are several dead pieces of bone situated at a distance from each other, each of them is generally accompanied with a distinct swelling and sinuses. Frequently these fragments are so concealed that they cannot be felt with a probe; but their existence may then be suspected, from the ulcers not healing, which can be ascribed to nothing else.

It is also necessary to distinguish with the greatest attention the different stages of the disease. The *first stage* may be considered as existing when the attack is yet recent, and the inflammation and its concomitant symptoms, the pain, swelling, and symptomatic fever, prevail in a high degree, and when no suppuration has taken place, or at least no discharge of matter. The *second period*, in which the dead bone is undergoing the process of separation, is indicated by a diminution of the inflammation, a partial subsidence of the swelling, and the discharge of purulent matter. When a probe is passed into the ulcers, the bone is felt bare and dry, and towards the limits of the swelling it is rough, where, as will be afterward noticed, an excavation is formed. Every part of the bone, however, [illegible] to be detached, still continues adherent to the rest of the living bone. At length the surgeon knows that the disease has reached its *last stage*, or that in which the dead portion of bone is entirely separated, when sufficient time for the completion of this separation has transpired, and when the dead bone can be distinguished with the finger, probe, or even the eye, to be loose and free from all connexions.

Although a necrosis must generally be classed with diseases which are serious and of long duration; yet the character of the disorder is not essentially bad, since it is often cured by nature, or with the assistance of surgery. Confident hopes of a cure may be entertained when the necrosis is confined to the external part of a bone; when it is simple and of moderate extent; when it is not situated in a bone destined for important uses, or near any viscus, or organ, that may be injured by it; and when it proceeds from an external cause, and the general health is good. On the contrary, the cure is difficult and the prognosis doubtful, when the disease is extensive, and complicated with other affections, either of the same or different bones; when it attacks bones which are of high importance on account of their functions or situation; when it is situated in the interior of the bone, and affects several parts of it; when it arises from an internal cause, for which there is no certain and quick-acting specific; when the patient is weakened by age or disease; and especially, when the sinuses extend into the neighbouring articulations.—(*Weidmann de Necrosi Ossium*, p. 22.)

The process of cure is said to take place with more celerity in the lower jaw than any other bone, and may be completed in three months. Mr. Russell has never known a necrosis of the tibia get well in less than a year; but in general nearly two years elapse first; and sometimes the case is protracted to a much greater length of time.

Necrosis of the lower jaw and clavicle never proves fatal: that of the lower extremities, which is the worst case, does so very seldom, and only from the violence of the first inflammatory symptoms, which rapidly bring on hectic fever, which proves incurable, unless its local cause be removed by timely recourse to amputation. When the violence of the first stage, however, has abated, the irritation ceases, and the hectic symptoms, if there are any, are generally moderate. Nor is this state of tranquillity disturbed, till the sequestrum, in making its way outwards, again produces irritation. At this second period of urgency, extensive inflammation may originate, ulcerations spread all over the surface of the limb, assume an unhealthy appearance, violent fever succeed, and the patient either perish or sink into a state in which he must consent to amputation, as the only means of saving his life. This is the last crisis of imminent danger; but in general it is less perilous than when the inflammation comes on in the incipient stage of necrosis.—(*Russell.*)

In the treatment of necrosis, the first grand object of the surgeon should be to aid nature in her endeavours to effect a cure, and not to disturb her operations by any superfluous or unseasonable interference. The second should be to assist her sometimes by the boldest proceedings, when she loses her way, and cannot by herself accomplish what is necessary.

But in order not to attempt any thing wrong, the surgeon must understand correctly what nature does in this disease; what it is in her power to perform; what she either cannot accomplish at all, or not with any degree of certainty; and, lastly, the circumstances in which she may err, and endanger the patient's life.

When a portion of bone dies, nature uses all her endeavours to bring about its separation from the part of the bone which still remains alive. Surgeons have denominated this process *exfoliation* (see *this word*), which resembles the separation of parts affected with gangrene and sphacelus from the living flesh. The exfoliation of bone, however, happens much more slowly than the separation of a slough of the soft parts. Neither are all exfoliations completed at a regular period; for they proceed most quickly during youth, when the constitution is usually more full of energy, the bones more vascular, and less replete with solid, inorganic, earthy matter. On the other hand, the process is slower in old, debilitated subjects, whose vitality is less active. A thin small scale of bone separates sooner than a large thick portion; and the most tedious exfoliation is that of a thick bone, from which a portion, including its entire diameter, is coming away. The separation of a necrosis takes place more expeditiously in bones of a light texture than in those of a solid structure; and sooner in the less compact parts of bones, such as the epiphyses and spongy substance, than in those of greater density.

When a necrosis has originated from the scurvy, syphilis, &c., and appropriate remedies are not administered, nature cannot effectually accomplish the process by which the dead bone is separated; the case becomes worse; and life endangered.

The separation happens precisely at the different points where the living and dead parts of the bone come into contact; and it is obvious, that the particles of the dead bone, which are at a distance from the part that retains its vitality, cannot be acted upon by it.

A variety of opinions have been entertained con-

cerning the means employed by nature in effecting this separation. Hippocrates believed that the dead part was pushed away by a fleshy substance which grew underneath it.—(*De Cap. vuln. cap.* xxiv.) Ludwig, Aitken, Bonn, and many others, adopted the same idea. —(See *Adversaria Med. Pract. vol.* 3, *p.* 63. *Systematic Elements of Surgery, p.* 287. *Thesaur. Oss. Morb. p.* 1.)

Van Swieten conceived that the dead part was forced away by the incessant beating of the arteries.—(*Comment. in Aphor. Boerrhavii*, § 252.) M. Fabre ascribed the separation to the extension and expansion of the vessels.—(*Mém. de l'Acad. de Chir. tom.* 4, *p.* 91.) Others supposed that the exfoliating piece of bone became loosened partly by the suppuration, and partly by the rising of the new granulations.—(See *B. Bell on Ulcers.*)

As Weidmann observes, there is unquestionably a reddish fleshy substance formed between the dead and living bone, and which Celsus has noticed under the appellation of caruncula.—(*De Medicina, lib.* 8, *cap.* 3.) But it would be erroneous to refer the expulsion of the dead portion of bone to it, since it can never be produced before a change has taken place in the structure of bone, there being in fact no space for it to grow in; and hence it is never seen before the disunion of the parts has considerably advanced. There must consequently be some other power which destroys the cohesion between the dead and living bone, and produces the groove, or interspace, in which the soft granulations arise. Besides, among other facts proving the falsity of the idea, that the granulations push off the dead bone, Weidmann particularly adverts to the occasional exfoliations of the whole circumference of a cylindrical bone. Here, if the granulations had the power of causing a disunion on one side, they could not have the same effect on the opposite one; but would tend to make the contact more intimate.

The separation also cannot be made by the pulsation of the small arteries, nor by the weak expansive motion of the vessels of the bone. Weidmann knows not what motives have induced certain writers to impute the effect to suppuration, and observes that, as the doctrine is not founded upon reasoning, it is superfluous to offer any arguments against it. If the least attention be paid to what nature really tries and accomplishes in this operation, nothing will be more manifest than that it is completed in a very different manner. Swelling first affects the periosteum and bone, which by degrees softens.—(*Vid. Troja, passim; Bonn. Thesaur. Oss. Morbos, p.* 122, *and Weidmann de Necrosi Ossium, tab.* 4, *figs.* 1 *and* 3.) At the margins of the necrosis, the bony surfaces, which were smooth, become rough and irregular. A fissure is there produced, which extends in every direction under the piece of bone that is about to be detached. The bony texture is also daily rendered less solid, so that the number of adhesions between the dead and living parts diminish, and in the end are totally destroyed. Weidmann then explains, that the true mode by which the separation is effected, consists in the absorption of the particles situated between the living and dead parts of the bone, in such a way, however, that the first loses a great deal of its substance; the last, scarcely any thing.—(*P.* 25.) After the dead bone has come away, the swelling of the periosteum subsides, and the living bone recovers its original hardness and solidity.—(*Troja, p.* 67.)

For a farther account of the process by which dead portions of bone are separated from the living, see *Exfoliation.*

When dead portions of bone are separated and loose, they still lodge in the cavities of the ulcers, and, like all other extraneous bodies, occasion irritation of the soft parts, and keep up a discharge of matter. Sometimes, however, nature of herself succeeds in expelling them. This happens in cases where the size and shape of the ulcer are calculated to facilitate the issue of the dead bone, which does not lie too deeply, and is propelled outwards by its own weight. In necrosis of trivial size, indeed, it is asserted that the small fragments of bone may be dissolved in the pus and come away with it (*David; Bousselin, Hist. de la Société Royale de Médecine, tom.* 4, *p.* 308; *Weidmann de Necrosi Ossium, p.* 26); but such an event can never be expected when the dead portion of bone is at all extensive.

The last thing which nature does is to restore the loss of substance which the bone has suffered. Although this operation is so extraordinary and wonderful that one might be disposed to doubt its reality, numerous examples, recorded in the annals of surgery, prove not only its possibility, but also its frequency.

In works referred to at the conclusion of this article, the following authors speak of the regeneration of a part, or the whole of the lower jaw bone: viz. Bonetus, Bayer, Guernery, Belmain, Acrel, Van Wy, Trioen, Bonn, Reiplein, Desault, Henkel, and Dussaussoir. A student showed Weidmann a lower jaw-bone, which had been thus regenerated and taken from the body of a man, whom the latter distinguished writer had been well acquainted with. The bone could not be freely depressed; yet it performed its functions tolerably well.

Moreau saw a case in which the clavicle was regenerated, and the new bone was presented by Dangerville, after the patient's decease, to the Academy of Surgery at Paris.—(*De Necrosi Ossium Thesis, Praes. F. Chopart, resp. P. G. Robert, Parisiis*, 1776.)

Chopart had an opportunity of witnessing the death and reproduction of scapula.

Weidmann saw an instance in which nearly the whole cylindrical shaft of the humerus perished and was afterward regenerated; a phenomenon that had been observed at earlier periods by Job of Meknen, Cajetano Taconi, E. Blancard, Duhamel, David, Acrel, Boehmer, Cheselden, and Vigaroux, whose respective works are cited at the end of this article.

Morand, Cheselden, and Bromfield published engravings respecting a reproduction of the upper part of the humerus, where the old dead bone was included in a sort of bony tube.

Regenerations of the ulna have been observed by Ruysch, Duverney, and Fowles.—(See *Thesaur. X. No.* 176. *Traité des Mal. des Os, Paris*, 1751; and *Phil. Trans. No.* 312.)

A similar reproduction of the lower ends of the radius and ulna was witnessed by Acrel.—(*Chirurgische Vorfälle von Murray, vol.* 1, *p.* 194.)

Similar reproductions of the thigh-bone are recorded by Wedel, Battus, Koschius, Hofmann, Scultetus, Diemerbroeck, Wright, Fabricius Hildanus, Raw, Dobyns, M'Kenzie, Ludwig, David, Bousselin, Larrey, Hutchison, &c., in publications specified at the conclusion of this subject.

The following case of necrosis of the thigh-bone is related by Dr. M'Kenzie. William Baxter, a boy thirteen years old, received a blow on his thigh at school, of which he at first hardly complained; but in a few months he began to have pain in the part, which inflamed, swelled, and appeared to have matter in it. The parents being poor, no surgeon was called, and the boy was allowed to linger for a great while. At length the matter made its way through the skin by a small opening, on the interior part of the thigh, about three inches above the knee, and a thin sanies continued to be discharged for eighteen or twenty months. The hole in the skin enlarged, and the point of a portion of bone began to protrude, and give a good deal of pain, when the clothes rubbed against it. After suffering in this manner for two years and a half, the boy, as he lay in bed one morning, felt the bone looser, and projecting more than ordinary. He gave it a strong pull, and brought the piece away entirely, which proved to be seven inches and a half of the thigh-bone. A good deal of bleeding followed; but the wound soon healed, and he had never afterward the least inconvenience. Dr. M'Kenzie, hearing of this singular case, sent for him, carefully examined his thigh, and found it as firm as the other. The only difference was, that it was somewhat thicker, and a little more curved. The muscles retained their natural softness and looseness on the bone. The detached piece of bone was a portion of its whole circumference.—(See *Med. Obs. and Inquiries, vol.* 2.)

We may infer, that the occurrence is more frequent in the tibia than any other bone, from the accumulated facts mentioned by Albucasis, La Marche, Muralto, De La Motte, Ellinchuys, Ruysch, Tacconi, Laing, Johnson, Hunter, David, Boehmer, Sigwart, Th. Bartholine, Hofmann, Saviard, Le Dran, Duverney, Trioen, Gunther, Ludwig, Michael, Bousselin, Weidmann, Russell, Whately, Desault, &c. See the works cited at the end.

Dr. Hunter describes a tibia which had been amputated. On examination, the case at first sight seemed to be a swelling of the whole bone, with a loose internal exfoliation. However, it proved to be a remarkable

instance of the separation of the greatest part of the original bone, whose place was supplied by a callus. The external surface of the enclosed loose piece of bone was smooth. A small part of the surrounding bony substance being removed, the contained piece was taken out, and found to be the whole body of the tibia. It had separated from the epiphysis at each extremity. The middle part of the bone had perished, consequently had lost its connexion with the periosteum, and was gradually thrown off from the living parts of the bone at each end. A callus, extending from end to end, united the two extremities of the original tibia, preserved the length and gave firmness and inflexibility to the limb. The exfoliation was so encompassed by the new bony case, that, though quite loose, it could not be thrown out.—(*Med. Obs. and Inq. vol.* 2.)

Weidmann saw a shoemaker, who, after much suffering, extracted, with his own hands, the greatest part of the diaphysis of the tibia; yet the loss was so well repaired, that the man could walk afterward nearly as ably as ever.—(*De Necrosi Ossium*, *p.* 29.)

"We are not to imagine (says Weidmann) that these regenerations happen by chance: experiments made upon living animals by Troja, Blumenbach, Koehler, Desault, and myself, prove that they invariably follow certain laws."

In fact, whenever the medullary structure of the long bones of pigeons or dogs is destroyed, these bones become affected with necrosis, and are afterward reproduced to the full extent of their destruction.

The observations and experiments cited by Weidmann also prove, that it is the long bones which are usually reproduced; though the flat ones are not entirely destitute of the power of regeneration, since experience fully evinces, that, when a portion of the skull is removed, either by a wound, by disease, or by the trepan, nature always endeavours to cover the deficiency, the edges of the aperture extending themselves by means of a bony substance, furnished by the periosteum, the dura mater, and cranium itself.–(*Tenon, Mém. de l'Acad. des Sciences*, 1758, *p.* 412, 413. 415, 416. 418.) But still the reproduction is imperfect, as an unossified place is always left, even when the bone has lost only a small piece, like what is taken out by the trephine; and when the destruction of the cranium is very extensive, no reproduction at all happens. This fact, which is proved by the observations of Saviard, Pott, Sabatier, &c. is particularly noticed by Sir A. Cooper.

When, in a case of necrosis, says Weidmann, a scale or table of either a long or flat bone is separated, no regeneration follows, because the granulations which rise up under the sequestrum then serve as a periosteum, and as soon as the dead bone is removed, they become united to the adjacent parts.

It is likewise ascertained that the power of reproduction in the bones is particularly active in the early periods of life, and in healthy subjects; and that it is languid and even annihilated in old persons, pregnant women (*Bonn's Thesaur. p.* 174), and in venereal, cancerous, and ricketty patients.—(*Callisen, Syst. Chir. Hodiernæ, pars* 1, *p.* 636.)

In order that a new bone may form, Weidmann thought that the periosteum and other membranes concerned in the nutrition of the original bone, must have been spared from destruction. In fact, says he, we observe, that in cases where the tube of a long bone has suffered necrosis, the bone is never reproduced, if the periosteum has been destroyed by inflammation or other causes. Surgeons ought also to understand, that it is not always a reproduction which has happened when a part of the bone perishes; not even when a tubular portion of a long bone dies and is contained in the medullary canal. For, according to Weidmann, if the innermost layers of a long bone perish, while those which compose, as it were, the bark, are preserved, the latter swell and soften as if they were actually a new bone. Several round apertures are observable upon their surface, which serve for the transmission of vessels, and are larger than those which perform this office in the natural state. Large openings or fistulæ are likewise formed, which, as in a new bone, lead to the medullary canal. Here it would be erroneous to conclude that a new bone has been produced; and a very little attention will discover that all is limited to some changes in the external part of the bone which the necrosis has not affected.

When, therefore, the interior of the canal of a long bone is destroyed by a necrosis which does not extend to the external layers, the case is not a reproduction of the bone.

When, however, we find the tube of any long bone included in a sort of osseous shell, and the surface of this tube smooth, like that of a bone in the natural state, we may be certain that it has been detached directly from the periosteum, and that the bony shell which contains it is a new production. On the contrary, if the surface of the dead tube be rough, we may infer, that the separation has taken place between the innermost layers of the bone, and those which are superficial, the latter composing now the osseous shell in which the sequestrum is included.—(*Weidmann de Necrosi Ossium*, *p.* 31.)

This last theory, concerning the production of the osseous shell in necroses of the long cylindrical bones, is adopted by Richerand as the true one, not only in the instances specified by Weidmann, but in every other example where the old bones seem to be included in another, which has the appearance of being a new production, and which was supposed by Troja, David, &c., to be formed by the vessels of the periosteum.—(See *Nosographie Chir. t.* 3, *p.* 158. 161, *ed.* 4.)

As far as Weidmann's information reached, the short or cuboid bones are not capable of reproduction.—(*P.* 31.) Duverney mentions an astragalus which was destroyed by necrosis; but does not state that any substitute for it was afterward formed.—(*Maladies des Os*, *p.* 458.)

Weidmann also never witnessed a reproduction of the spongy substance, such as it was before its destruction, round the medulla. He always found the substituted matter dense and compact, at least for some time after its formation.

It is now admitted, however, that in process of time the inner surface of the new bone becomes cellular, and is lined with a membrane containing medulla. The regeneration of the medulla was first observed by Koehler, and afterward by Dr. J. Thomson, in an extensive series of experiments which he made with Dr. Alexander M'Donald, and which were published in the latter gentleman's inaugural dissertation in 1799.—(See *Thomson's Lectures on Inflammation*, *p.* 393.) Mr. Russell was not aware of the regeneration of the medulla; for he states, that after the absorption or removal of the sequestrum, the cavity of the new bone becomes filled up with granulations which are at length converted into bony matter. Thus, he says, the new bone differs from the original one, in being solid instead of hollow. Authorities, however, are decidedly against Mr. Russell on this point: in the 5th vol. of the *Mém. de l'Acad. de Chir.* is the history of a man, the whole of whose clavicle came away, without his being deprived of any of the motions of the arm. The death of this patient, which happened shortly afterward, afforded an opportunity of examining how nature had repaired the loss. Another clavicle was found regenerated, which neither differed from the original one in length nor solidity; but only in shape, being flatter, and not so round. It was connected with the acromion and sternum just like the primitive bone.

The power which thus reproduces bones is only a modification of that which unites fractures. Indeed, what consolidates broken bones, and is known by the name of *callus*, presents all the characters of new bone, begins and grows in the same way, and may be impeded and retarded in its formation by the same causes.—(See *Callus* and *Fractures*.) It is farther highly probable, as Weidmann remarks, that the power which effects the reproduction of bones, is the same as that which, in the sound state, nourishes and supports these parts. But to what organ appertains the function of reproducing bones?

Many able men have ascribed the whole work to the periosteum. (*C. Havers; Duhamel, Mem de l'Acad. des Sciences*, 1739, 1741, 1742, 1747. *Fougeroux, Mém. sur les Os; Paris*, 1760. *Swencke, Harlemer, Abhandlungen, th.* 1, *p.* 39. *Bertin, Osteologie Marigues, Abhandlung von der Natur und Erzeugung des Callus*, *p.* 199.)

Haller (*Elém. Physiol. t.* 8, *p.* 352), Callisen (*Collect. Hafn. t.* 2, *p.* 187) Tenon (*Mém. de l'Acad. des Sciences*, 1758, *p.* 415), Bordenave (*Mém. sur les Os*, *p.* 227), and many others, have seen a part of the new production spring up from the substance of the old

bone; a thing, says Weidmann, which one is also led to believe by the fact, that, when the whole tube of a long bone is affected with necrosis, the epiphyses, which remain sound and untouched, unite and grow to the new tube, though no periosteum exists in the situation of the union.

Nor does Weidmann think, that the specimen of a fractured thigh, of which Blumenbach has published an engraving, proves the contrary.—(*Geschichte und Berschreibung der Knocher; Göttingen*, 1786, *tab.* 1, *fig.* 1.) This preparation exhibits a union, which had taken place by means of a very broad osseous ring, encompassing the ends of the fracture, which lie far asunder. The event appears to Weidmann to have been the result of rachitis, or lues venerea, with which the young patient, according to Blumenbach himself, had been affected, and by which the nutrition of this bone had been disordered. For, says Weidmann, in other examples of united fractures the ends of the bone are so connected together by the callus, that there does not exist a single point between them where this substance is not effused, and the medullary canal itself is obstructed and filled with it. In the *Journ. Complém. du Dict. des Sciences Méd. t.* 8, may be found some considerations offered by Larrey against the doctrine, that the periosteum is the organ of ossification.

Paletta records a case, in which five inches of the tibia were regenerated; and he concludes, that the new osseous substance was not formed from the periosteum, which had been destroyed, but from the remaining portion of healthy bone.—(See *Exercitationes Pathologicæ*, 4*to. Mediolani.*) Dr. R. Knox has also seen an instance of caries of the trochanter major, where nature had attempted to repair the injury by a secretion of new bony matter round the ulcerated part of the bone, and where the new osseous substance was evidently formed by the vessels of the old bone, the periosteum remaining perfectly sound and unchanged. His remarks are all in favour of the doctrine which refers the production of new bone to the vessels of the remaining portion of living bone.—(See *Edinb. Med. Surg. Journ. vol.* 18.) The concurring opinion of Mr. Liston, on the same point, I have mentioned in another place.—(See *Fracture.*) And Mr. B. Bell has very recently expressed his agreement with those authors, "who do not assert, that the periosteum is endowed with such complicated functions as to be able, not only to repair its own lesions, but at the same time to secrete osseous matter." The membrane that lines the cavity of the new bone, he also observes, differs from the periosteum in being less dense and fibrous.—(*Obs. on Diseases of the Bones*, *p.* 54, 55.)

That, however, the periosteum is frequently the organ of the reproduction of the bones, seems proved by the experiments of Troja, Blumenbach, Desault, and Koehler, since in these the bones were invariably regenerated, though there was nothing left of the old bone that could furnish the new reproduction, except the periosteum.

If we examine the new bone at different periods of its developement, it appears in the earliest state in the form of a reddish fluid, as has been observed by Duhamel, Fougeroux, Bordenave, Haller, Callisen, and others. If we also attend to the progressive changes which this fluid undergoes, we cannot but believe that, as in the embryo, an organic and fixed arrangement of parts takes place. Indeed, it would be erroneous to consider such fluid as destitute of organization and extravasated at random. Thin and little in quantity on its first appearance, its consistence and quantity afterward gradually increase (*Troja*, *p.* 42, 44), so that what at first appeared like a liquid, soon becomes a gelatinous substance, in which are developed, especially at its inner surface and towards its lower part, bony fibres which incessantly become more and more numerous. These fibres in a short time form little layers and cells, and extend themselves every where, so that at length all which was fluid disappears, and the new bone is produced. While young, however, it is still spongy and reddish (*Troja p.* 44), but soon becomes denser, harder, and more solid, than that was for which it is a substitute, and it acquires the ordinary colour of the rest of the bones.

The external surface of the new bone, which, during the period of its formation, was irregular and studded with several excrescences of various sizes, and pierced with apertures of different dimensions, becomes in the course of time smooth and regular, especially after the expulsion of the sequestrum.

The sides or walls of the new bone, which at first were of considerable thickness, in time also grow thinner.—(*Troja*, *p.* 21.) When the entire dead bony cylinder continues in its cavity, the new bone is neither shorter nor longer than the original. But should one of the ends of the dead tube protrude from the cavity while, by the side of the affected bone, there is not another one capable of resisting the action of the muscles, the new bone will be shortened, and undergo some change in its shape and direction. Indeed, says Weidmann, the new bone in its early state, from want of consistence, must yield to the efforts of the muscles.

Its shape is not exactly like that of the original bone: the sides are flatter; the usual angles, depressions, and eminences are not observable, and sometimes others are formed.

How admirable is the process by which the muscles, detached from a bone affected with necrosis, have other insertions given to them, and are thus rendered capable of performing their functions.—(*Troja*, *p.* 27.)

The periosteum, which swells as soon as the exfoliation of the old bone commences, shrinks, and is not at all thickened when the exfoliation is finished. Troja, having destroyed the medullary structure of a long bone, found the periosteum swelled at the end of 36 hours; but he observed that the whole of such swelling disappeared before the 25th day.—(*P.* 43. 67.)

The periosteum which thus survives adheres to the new bone as it did to the old one; its vessels, which are now increased in diameter, and convey a larger quantity of blood, dive into large apertures in the regenerated bone, ramify every where in its substance, and nourish it.

Dr. Macartney's observations nearly agree with those of Troja and Weidmann respecting the formation of the new bone by the periosteum, with this difference, however, that he does not describe the original periosteum as becoming afterward attached to the new bone, but as disappearing. Dr. Macartney remarks, "that the first and most important circumstance is the change which takes place in the organization of the periosteum: this membrane acquires the highest degree of vascularity, becomes considerably thickened, soft, spongy, and loosely adherent to the bone. The cellular substance, also, which is immediately connected with the periosteum, suffers a similar alteration: it puts on the appearance of being inflamed, its vessels enlarge, lymph is shed into its interstices, and it becomes consolidated with the periosteum. These changes are preparatory to the absorption of the old bone, and the secretion of the new osseous matter, and even previous to the death of the bone which is to be removed. In one instance I found the periosteum vascular and pulpy, when the only affection was a small abscess of the medulla, the bone still retaining its connexion with the neighbouring parts, as it readily received injection. The newly organized periosteum, &c. separates entirely from the bone, after which it begins to remove the latter by absorption;" and while this is going on its inner surface becomes covered with little eminences resembling granulations. "In proportion as the old bone is removed, new osseous matter is dispersed in the substance of the granulations, while they continue to grow upon the old bone, until the whole or a part of it is completely absorbed, according to the circumstances of the case. What remains of the investment after the absorption of the old bone and the formation of the osseous tube which is to replace it, degenerates, loses its vascularity, and appears like a lacerated membrane. I have never had an opportunity of examining a limb, a sufficient time after the termination of the disease, to ascertain whether the investment be at last totally absorbed; but in some instances I have seen very little remaining. During the progress of the disease, the thickened cellular substance which surrounded the original periosteum becomes gradually thinner; its vessels diminish, and it adheres strictly to the new-formed bone, to which it ultimately serves as a periosteum." Dr. Macartney states, that the anatomical preparations which authenticate the above observations were preserved at St. Bartholomew's Hospital.—(See *Crowther on White Swelling*, *p.* 183, *ed.* 2.)

Mr. Stanley, however, lately showed me in the same museum a preparation which tends to confirm the ac-

curacy of Troja's account of the old periosteum becoming adherent to the new bone. In this example the periosteum is perfectly continuous with that covering the epiphyses. If this were not the fact, we should have to explain in what way the periosteum of the new bone is formed. We know that the vessels of the original periosteum enter the new bone, in order to complete its formation; and it seems more consonant with the uniform simplicity of nature's operations, to suppose that this connexion is kept up, than that the old periosteum should be totally removed after the production of the new bone, and another membrane of the same kind be then generated.

An interesting example of necrosis of the thigh bone, published some time ago by Mr. C. Hutchison, tends also to prove that the new osseous shell is commonly formed by the periosteum, as in this case the medullary bags or cells were found completely ossified (*Practical Obs. in Surgery, p.* 135), and could not therefore be supposed to be capable of the work. Among the moderns, Dr. M'Donald deserves to be mentioned as one of the most distinguished advocates for the truth of Troja's explanation of this subject.—(See *M'Donald's Thesis de Necrosi ac Callo; Edinb.* 1799.) Another late writer has adduced many arguments to prove that the pulpy mass which extends from one epiphysis to the other, and is itself at last converted into bone, is formed quite independently both of the original bone and of the periosteum.—(See *Russell's Practical Essay on Necrosis, p.* 27, *Edinb.* 1795.) This account, however, is contrary to the observations of Troja, David, Weidmann, M'Donald, Macartney, and numerous other observers. Indeed, Mr. Hutchison seems to think the periosteum so essential to ossification, or the production of a new bone, that he attempts to explain the cause of fractures of the patella not becoming united by a bony substance, by adverting to the deficiency of periosteum upon it; a circumstance which he deems also a strong argument against Mr. Russell's doctrine. —(See *Practical Observ. in Surgery, p.* 141, 142.)

These very same cases, however, fractures of the patella, do sometimes unite by bone, and therefore, while Mr. Hutchison is urging them as facts against Mr. Russell's opinion, Baron Larrey is actually adducing them in its support.—(See *Journ. Complém. du Dict. des Sciences Méd. t.* 8.) The experiments of Breschet and Villermé (see *Fracture*) are decidedly against the periosteum being exclusively the organ of ossification.

Boyer does not refer all the work of reproducing bones exclusively to the periosteum in every instance; but joins Weidmann in believing, that what seems a new bone is sometimes only a separation and thickening of the external layers of the original bone, which have escaped destruction. He notices the modifications to which the phenomena of necrosis are subject when the disorder affects the whole thickness, and the whole or the greater part of the circumference of a long cylindrical bone. When the periosteum is destroyed together with the bone, and the medullary membrane, which does the office of an internal periosteum, is preserved, Boyer represents the latter membrane as undergoing similar changes to those which we have mentioned as taking place, under other circumstances, in the external periosteum, and he describes it as becoming the organ by which the new bone is formed.—(See *Traité des Maladies Chir. t.* 3, *p.* 432.) But when the whole thickness and circumference of a long bone are destroyed, together with the medullary membrane, while the periosteum survives, Boyer agrees with Troja, &c. in believing the latter membrane to be the means by which the new bone is generated.

The internal surface of the new bone is lined by a new membrane, which serves as a periosteum, and is at first hardly distinguishable.—(*Troja, p.* 56.) In the early state, it is soft and pulpy (*ibid. p.* 22); but, by degrees, it grows thicker and firmer, and is at length converted into a true membrane, which sends a great number of vessels into the substance of the bone. When this membrane is torn off, the surface which it covered is found somewhat smooth, the edges of the bony layers and projections of the fibres being blunt and rounded.

The cavity of the new bone includes, and almost entirely conceals, the dead fragments. Sometimes, however, the new bone forms a sort of bridge over the sequestrum, in such a manner that the cavity is open above and below, in both which situations the sequestrum can be felt.—(*Hunter, in Med. Obs. and Inquiries, vol.* 2, *p.* 418.)

Sometimes it is only a narrow cross-piece, which forms the bridge retaining the sequestrum.—(*Weidmann, vid. tab.* 5, *fig.* 1, *a.*)

The new bone may also have an opening in it, out of which the dead portion protrudes.—(*Ib. p.* 35.)

Sometimes the cavity of the new bone is single: while, in other instances, there are several successive cavities in the direction of the length of the bone, with transverse interspaces between them; or else the cavities are situated laterally with respect to each other, and divided by partitions.—(*Weidmann, tab.* 7, *fig.* 2.)

These cavities are proportioned in size and shape to the fragments of dead bone which lodge in them. It occasionally happens, that they open into some neighbouring joint, and bring on suppuration there: a very unfavourable complication.—(*Ibid. p.* 34, *and tab.* 6, *fig.* 3; *also Boyer, Traité des Mal. Chir. tom.* 3, *p.* 435.)

Let us next follow Weidmann, and take notice of the holes, by which the cavities including the dead pieces of bone open externally, which Troja denominated the large foramina, and which the preceding excellent writer preferred calling the *cloacæ*, because they serve to convey outwards the matter and any separated pieces of bone. In the beginning of the disorder they are not observable, a certain space of time appearing to be requisite for their formation. They are noticed in long cylindrical bones, whether original, or of new production, whose cavities contain dead fragments.

These openings vary in number; when the sequestrum is small, only one is found; but when the piece of dead bone is extensive, there may be two, three, or four. Weidmann never saw more than five. But Troja met with eight.—(*P.* 58.) Weidmann possessed a small portion of the diploe of the os innominatum, which was affected with necrosis, and contained in a bony cavity, that had no external opening whatever.

When there are several distinct cavities in the same bone, containing dead fragments, each cavity has at least one external opening.

These *cloacæ*, or apertures, are commonly situated at the lower and lateral parts of the cavities; pass obliquely outwards; and communicate with fistulous ulcers, which open on the surface of the skin.—(*David, p.* 186.) Some of the cloacæ, however, form at the middle, or (what is exceedingly rare) at the upper part of the cavities, and proceeding outwards, without any oblique track, go to the front, back, or lateral parts of the limb.

They are of a round or oval shape, or nearly so. Their usual size is such that it will just admit a quill, and they vary very little from this dimension.

They terminate internally by converging approaching edges, in the manner of a funnel; while, on the contrary, the margins of their outer extremity expand. The canal between these two orifices is sometimes long, sometimes short, and, in certain cases, of no extent at all.

Different opinions have been broached respecting the causes which produce the apertures in the new bone, termed by Weidmann the *cloacæ*.

M. David says that the pus, collecting in an early stage of the disease between the bone and the periosteum, distends and corrodes this membrane, and that the openings which form in it become afterward a cause of fistulæ in the new bone.—(*P.* 186.) But it is observed by Weidmann, that this explanation is inadmissible, since the existence of the collection of pus, mentioned by M. David, is not proved by observation: in fact, it was never met with by Troja, Blumenbach, Desault, Koehler, and many others, in repeated experiments on the subject.—(*Troja, p.* 56 *and* 66; *Weidmann, p.* 36.)

Koehler thought he had seen the new bone itself destroyed by the pus, and *cloacæ* thus produced.—(*P.* 68—72.)

Weidmann, however, deems this opinion quite as improbable as the preceding, for the fact of the surface of these bony apertures being always smooth, always formed in one manner, and constantly lined by the periosteum, decidedly proves that they cannot arise from erosion.

Troja, in his third experiment upon the regeneration

of bones, remarked, that forty-two hours after the destruction of the medulla, there took place, between the bone and the periosteum, an effusion of lymph, which was at first thin and in small quantity, but afterward became thicker. He noticed, in the midst of this gelatinous substance, *some small spaces, where it was deficient, and which had, instead of it, a subtle, whitish, dry incrustation, which, though tolerably adherent, could be rubbed off. These small spaces, according to Troja, produce the apertures called the cloacæ.* —(*Troja, p.* 45.)

In another experiment, he had an opportunity of examining the above little spaces at the end of forty-eight hours: he affirms that they were replaced by the large apertures or cloacæ of the new bone (*P.* 47), and that such openings were invariably formed in the place of the small incrusted spaces already described. —(*P.* 58.) As Troja took notice that no lymph was effused at these particular points, he was inclined to impute the circumstance to a defect in the ossification, and, *perhaps, to the death of some parts of the periosteum.* Weidmann acknowledges that the mode in which the formation of the cloacæ happens is exceedingly obscure; and expresses his belief that Troja's account of it is the nearest to the truth. But, says he, one thing is certain, namely, that these openings have no other use but that of conveying outwards the pus, which collects in the cavity, and the small bony fragments, since, as soon as every atom of dead bone has passed out, they diminish, and, at length are totally obliterated.—(*Weidmann, De Necrosi Ossium, p.* 36.)

It is a remarkable circumstance in the history of necrosis, that, in favourable instances of the disease, the inflexibility and firmness of the limb are preserved, during the whole of the process by which the new bone is formed. Consequently the new bone must have begun to grow and have acquired firmness before the old bone separated or was absorbed. Were this not the case, the limb must become flexible and useless the moment the dead bone is removed. Another consequence of the new bone being formed before the removal of the old one, is that the former must surround and include the latter. For, since the lifeless portion of bone completely occupies the space between the two living ends, these cannot be immediately connected by the new bony matter. The connexion can alone be completed by the new bone being deposited on the outside of the old one, from one end to the other, and attaching itself to the portions which still remain alive. The new bone must also be necessarily larger than the old one, because externally situated; and hence the affected limb, after the cure is complete, will always continue larger, clumsier, and less shapely than the other. The length of it, however, remains unaltered, because the old bone retains its attachment, while the rudiments of the new bone are lying on its outside, and connect the living ends of the old one, by an inflexible mass, equal in length to the portion which is destroyed.

Thus we see, that in the process which nature follows in the formation of the new osseous shell, the old bone serves as a mould for the new one, and the first step of the process is to surround the old bone with an effusion of coagulating lymph.—(See *Russell on Necrosis, p.* 2—7.)

When the sequestrum is thrown off slowly, the inflammation is moderate; but when it separates quickly, while the new bone is in a soft state, the detachment is always preceded by severe inflammatory symptoms, and followed by a temporary loss of the natural firmness of the limb. This premature separation of the sequestrum often occurs in necrosis of the lower jaw, and the chin consequently falls down on the neck. In certain cases, the sequestrum separates at each end from the living portions of the old bone, before the new osseous shell has acquired firmness, so that the limb feels as if it were broken in two places.—(*Russell.*)

Let us next consider the states and circumstances of necrosis, in which the art of surgery may be advantageously exerted in the assistance of nature, and the means which may be employed for the purpose.

A common error of medical and surgical practitioners is always to impute the cure of every disease to whatever remedies happen to be employed, and successes are too often boasted of, the merit of which belongs entirely to nature. It is, indeed, not very unfrequent to hear remedies panegyrically spoken of, which counteract the salutary efforts of nature, who, in this case, is obliged to overcome both the disease and the irrational treatment which is applied to it. As Weidmann observes, this erroneous mode of considering things has happened particularly often among surgeons who have had cases of necrosis under their care, all of whom boast of the cures which they have accomplished, although some employed absorbent earths; others, aromatics; some, spirituous applications; others, balsams; some, acids; others, caustics; and some, armed with a wimble, made numerous perforations in the dead bone; while many others rasped the part, or attacked it with the trepan, cutting forceps, the gouge and mallet, or even the actual cautery; and a certain number did nothing more than apply dry lint. Nature, who was favourable to all, did her own work in silence, whatever were the remedies employed for her assistance: whether mild and inert, acrid and corrosive, or hurtful and improper.

We have already noticed, that a dead portion of bone separates from the living exactly in the same way as gangrenous soft parts spontaneously drop off without the interference of art. The separation happens precisely at the points to which death has extended; limits which are well understood only by nature, and of course can be measured only by her. Art would incur great risk of either going beyond them, or else of not reaching them at all. Perhaps it may be deemed unsafe to confide the process of separation or exfoliation to nature. But in what other manner could it be more safely accomplished, without hemorrhage or pain to the patient—without any risk of a recurrence of inflammation, or of a fresh necrosis?

Is there reason to fear, that when every thing is left to nature, the separation cannot be finished till after a very long period of time? It is true, says Weidmann, that the process frequently requires a considerable time; but as the vitality of the bones is not possessed of much energy, and their component parts strongly cohere, slowness is inevitable in an operation which depends entirely upon the vital power. What is it then which surgery can do to accelerate the process?

Will any of the above-mentioned topical applications have this effect? They are put upon the inert surface of a dead piece of bone, in which no vital power or action can be again excited. When acrid, they prove irritating, inflaming, and destructive of the neighbouring flesh, without any utility—and cause pain to the patient, which is compensated by no good. Would the perforations recommended by Celsus, Belloste, and many others, have the desired effect? If, says Weidmann, they are confined to the dead bone, they cannot have more effect than the scarifications which were formerly practised by ignorant surgeons in cases of gangrene; and, if they extend to the living bone, this will be injured, or at least run the risk of being so. Lastly, Weidmann demands, if the separation can be accelerated by the actual cautery, which cannot act upon every point of the necrosis, and which, unless applied with the greatest precautions, will burn the subjacent parts, and bring on a new attack of inflammation, without forwarding the exfoliation in the smallest degree?

Of what use can rasping and scraping instruments be, which act merely upon the dead parts? Or will the gouge, and other cutting instruments, do more good? They cannot take away the whole of the dead portion, without injuring the adjacent living bone, and causing a risk of another necrosis. And if they leave any pieces of the old dead bone behind, nature will be as long in effecting the separation of these, as she would have been in detaching the entire necrosis.

Weidmann mentions a case which occurred in the hospital of St. Roch at Mentz. A man's legs were seized with mortification in consequence of exposure to cold; the whole of the dead parts separated; and the bones were sawn through on a level with the living flesh. A portion of the end of each bone, however, was afterward thrown off altogether by nature; and Weidmann thence concludes, that the previous use of the saw had been fruitless. Weidmann then cites another case of mortification of the leg and half of the thigh, which was the consequence of a putrid fever. The leg sloughed away, leaving the lower portion of the thigh-bone uncovered and projecting. Under a tonic plan of treatment, this part of the bone sprouts

neously separated. As, however, a considerable quantity of integuments had been destroyed, the ulcer was slow in healing; but it cicatrized at last, and the young woman continued well long afterward.

Weidmann has quoted the memorable case in which Mr. C. White first sawed off the upper part of a diseased humerus.—(See *Amputation.*) As in this instance nature accomplished of herself the separation of another dead portion of the same bone, two months after the operation, Weidmann seems disposed to think the cure would have happened equally well without it.

In cases of slight superficial necrosis, surgeons have frequent opportunities of trying every kind of topical application; and when the cure takes place during the use of any of them, the benefit is ascribed to whatever happens to be in use. But, says Weidmann, in numerous more serious examples of necrosis, it is impossible to make these applications reach the whole surface of the dead bone; but, notwithstanding this circumstance, the separation is not impeded. Some exfoliations happen, without our knowing of their occurrence, and without a thought having been entertained of promoting them by any vaunted applications. We even see necroses separate, whose situation rendered them inaccessible to our remedies: such are the necroses which occur within the long bones, and comprehend the whole of their cylindrical shaft or body. What surgeon can boast of having effected, by topical applications, the separation of the whole lower jawbone? a thing which nature has very frequently accomplished. And when, as often happens, the entire diaphysis of the thigh-bone, tibia, or other long bone, comes away; or, split longitudinally, such bone loses a half of its cylinder; how is it possible for any topical applications to reach every point at which the separation occurs?

The internal remedies, such as asafœtida, madder, sarsaparilla, hemlock, belladonna, onopordum, lime-water, &c. recommended by numerous practitioners, have in reality no direct efficacy in promoting the separation of necroses: if, says Weidmann, they do any good, it can only be by their tonic and alterative qualities, or rather by keeping the patient amused, so as to gain the requisite time for the completion of the process of exfoliation. The employment of all these ineffectual means, Weidmann conceives, must have originated from ignorance of the process followed by nature in separating dead portions of bone, and from ascribing to the arterial pulsations, or the power of the granulations, what certainly depends upon the action of the absorbent vessels.

A question here naturally presents itself—Would there be any utility in exciting by stimulants the action of the lymphatic vessels, in order to accelerate the separation, of which it is the efficient cause?

Weidmann thinks that very beneficial effects might result from the plan. But, he asks, what means should be used for this object? Cold? Purgative medicines? Repeated vomits? Squills? Camphor? Neutral salts? Issues?—(Vide *Wrisberg, Comment. Soc. Reg. Gött. vol.* 9, *p.* 136, 1789.) The internal and external employment of the preparations of iodine, a medicine which has extraordinary power in increasing the activity of the absorbents, might deserve a trial.

The reasons already detailed, and a variety of experiments successfully made by Weidmann, lead him to set it down as an established principle, that the separation of a necrosis is almost entirely the work of nature, and that surgery can do very little in the business.

Ignorance of this important fact paved the way to the wrong practice of making incisions, for the purpose of exposing the whole surface of a necrosis, immediately the existence of the disorder was known. As such incisions very soon closed up again, so as to leave only a small outlet for the matter, they were in many cases repeatedly practised before the dead bone became loose.

The avowed design of the incisions was to make room for the topical remedies which were to render the exfoliation quicker; but as these remedies possess no real efficacy, it follows, that making incisions before the dead bone is loose, only torments the patient without producing the least benefit.

The orifices of the ulcers, then, which allow the discharge to escape freely, are, says Weidmann, sufficient as long as the fragments of bone are not entirely detached, and the surgeon should all this period abstain from the use of the knife.

Although Weidmann condemns every mode of treatment which is inefficacious, painful, and sometimes even hurtful, he would not have it supposed that he altogether rejects all assistance from medicine. On the contrary, he approves of all those means which are consistent with the views of nature, which really assist her, and do not tease the patient to no purpose. In short, says he, *the indications are limited to removing the original cause of the disease; to alleviating the symptoms; to supporting the patient's strength, and improving the state of the constitution, in whatever respect it may be bad; and, lastly, removing the dead portions of bone when they become loose.*

Above all things (continues this sensible practitioner), the surgeon must not regard every piece of exposed bone as necessarily affected with necrosis, and, in consequence of such idea, have recourse to acrid, drying, caustic applications. Such means are not only useless, but absolutely pernicious; because they may actually cause a necrosis which did not exist before they were used, and which would not have taken place at all if only mild simple dressings had been employed.

When the disease presents itself with violent symptoms, the inflammation and fever being intense, the severity of the case is to be assuaged by low diet, antiphlogistic remedies, emollient applications, and venesection in moderation, the disease being one which is of long duration, and apt to wear out the patient's strength. Here, perhaps, topical bleeding ought always to be preferred to venesection. When the necrosis has arisen from syphilis, scrofula, or scurvy, &c. the medicines calculated for the cure of these affections must be exhibited ere any favourable changes can be expected in the state of the diseased bone.

Lastly, it is the duty of the practitioner to extract the fragments of dead bone, in order that the deficiencies produced by them may be filled up, and the ulcers of the soft parts heal.

Nature, who succeeds by herself in detaching the dead pieces of bone, can do very little in promoting their passage outwards. Frequently, indeed, she has no power at all in this process, and it is only from surgery that assistance can be derived. When a dead piece of bone is still adherent at some points, its extraction should be postponed until it has become completely loose. If it were forcibly pulled away, there would be danger of leaving a part of it behind, which must have time to separate ere the cure can be accomplished.

But when a fragment is entirely detached, and the orifices of the sores are sufficiently large, it is to be taken hold of with a pair of forceps, and extracted.

When the ulcer has only a very narrow opening, suitable incisions must be practised, in order to facilitate the removal of the loose dead bone.

Sometimes the dead fragment protrudes from the ulcer, and projects externally, so that, if loose, it admits of being taken hold of with the fingers and removed. In this way Weidmann took away a large dead piece of the humerus, which protruded nearly two inches out of an ulcer in the middle of the arm. The patient was a young lad, fourteen years of age; and the limb concave within, convex externally, thicker and one inch shorter than its fellow. He got quite well three weeks after the removal of the dead bone.

We have already adverted to the example recorded by Weidmann, in which a shoemaker removed by himself nearly the whole body of the tibia. Doubtless, the projection of the bone, and its looseness, enabled the man to do this easily with his fingers. But there are cases which present more difficulty: such are those in which the sequestrum is included in a cavity either of the original or new bone.

The old surgeons were in the habit of amputating limbs which were in this state; although instances were not wanting in their days to prove the possibility of relieving the disease without amputation. This blameable custom of removing every limb thus affected is justly exploded from modern surgery. Albucasis was the first who attempted to cure such a necrosis by the judicious employment of the knife and saw.—(*Lib.* 2, *cap.* 88.) The same kind of practice was successfully adopted in two instances by the celebrated Sculletus. —(See *Armament. Chirurg. tab.* 46, *and obs* 81.) This

commendable method, however, afterward fell into disuse, until M. David, by twenty examples of success, refuted all the objections which had been urged against it.—(*P.* 197.) Since the period of this distinguished author the practice has been imitated by all enlightened surgeons, so that the case is no longer regarded as a disease necessarily requiring amputation. M. Bousselin cut out the sequestrum eight times from the tibia and four times from the thigh-bone with perfect success.—(*Vide Mém. de la Société Royale de Medecine*, *t.* 4.)

The method consists in exposing the bone, and making in it an opening of sufficient size for the removal of the loose dead fragments.

Experience has proved, not only that patients affected with necrosis easily bear this operation, but also, that after its performance, the ulcers commonly heal very favourably, the health becomes re-established, and the functions of the part affected are hardly at all impaired.

Surgeons, however, are not indiscriminately to choose any period for doing the operation. If they are too hasty, they will run a risk of finding the dead portion of bone still adherent to the adjacent parts: and if they delay too long, the patient may be irrecoverably reduced, while the new bone, on account of the hardness which it has now acquired, cannot be so easily perforated.

Patients are met with who have been afflicted with necrosis several years. In such cases great circumspection is necessary, and the practitioner should carefully endeavour to ascertain that the dead pieces of bone have not been absorbed, nor come away piecemeal in the discharge, lest a useless operation should be done, as once happened in the practice of M. Bousselin.—(*Mém. de la Société Royale de Médecine*, *t.* 4, *p.* 304.) Therefore, when the disease is of long continuance, when the discharge is much less than it was at the commencement, when small pieces of bone have at times been voided, and the sequestrum cannot be felt with a probe, it is doubtless, says Weidmann, most prudent to abandon all idea of operating, and allow nature to finish what she has so well begun. In short, when the sequestra are undergoing a gradual absorption without ever making their appearance externally, or giving any considerable disturbance to the constitution, or when the dead bone is making its way outwards without occasioning urgent inconveniences, the surgeon should interfere very little with the natural progress of the case. When the dead bone does not tend to make its way through the skin, but lies quietly concealed in the new osseous shell, extensive suppurations may be prevented, by occasionally applying leeches, and keeping open a blister with the savine cerate, as recommended by Mr. Abernethy in his Lectures, and Mr. Crowther in his work on the White Swelling. The blister will at the same time have great effect in promoting the absorption of the sequestrum, and of course in accelerating the progress of cure.

If the surgeon operate as soon as the sequestrum becomes loose, he will find the new bone so soft that it can be divided with a knife; a circumstance which materially facilitates and shortens the operation.

Keeping in mind the foregoing precepts, the surgeon is to begin with exposing the bone in which the sequestrum is contained. When the bone lies immediately under the skin, Weidmann recommends making such incisions as will lay bare the whole of its surface; and when its situation is deeper beneath the muscles, he even sanctions cutting away as much of the flesh as may be necessary to allow the instruments to be freely worked upon the bone. I cannot, however, see the propriety of this advice: exposing the whole surface of the bone in the first instance, before it is known whether the saw need be so extensively used as to require such a denudation, certainly appears irrational. And as for cutting away any portions of muscle, this can be no more necessary here than it is in the operation of trephining. But it is unquestionably proper to make with the bistoury sufficient space for the use of whatever instrument is employed for the division of the bone. Yet it is only necessary to make this exposure in the first instance in one place. The surgeon can afterward enlarge the incision, or practise others, as circumstances may indicate. The surface of the bone being brought into view, if the cavities in which the dead fragments lodge present apertures which are too narrow, these apertures must be rendered larger by means of small trephines, or saws constructed on the principles of those described by Mr. Hey, of Leeds. The perpendicularly acting wheel-like saw, turned by machinery, and invented by Mr. Machell, here promises also to be of important assistance. It has been used by Sir A. Cooper, who has given an engraving of it in his *Surgical Essays*, *part* 1, *pl.* 8, *fig.* 7. And another saw, constructed on somewhat similar principles, has been employed by Graefe of Berlin with great advantage for several years. A tract by Schwalb (*De Serra Orbiculari*, *4to. Berol.* 1819), giving an account of it, was sent to me by the late Dr. Albers a little before his death: it is turned by means of a handle which projects horizontally from the cutting part of the instrument, and it has a frame or fulcrum on which it works. Professor Thal's rotation-saw, and Mr. Liston's bone-forceps may also prove of essential service.—(See *Edinb. Med. Journ. No.* 78.)

With such instruments, the pieces of bone extending across the above openings, and impeding the extraction of the sequestra, may likewise be removed.

But when the preceding cavities are closed on every side, and it is impossible to reach into them in any other way than through the cloacæ, a trephine is to be applied, which must comprise within its circle a half of the fistulous opening. The crown of the trephine, however, must not be broader than the cavity of the bone, nor yet narrower than the sequestrum.

If, after making a perforation in this manner, the sequestrum should be found too large to pass through the opening, a small saw must be employed for enlarging the aperture. When the bone is so hard and thick, that it cannot be well cut with a saw, the surgeon has the sanction of authority and experience, for using a gouge and mallet.

When the sequestrum is found to be very large, it will be necessary to expose more of the surface of the bone by incisions. In this sort of case, Weidmann recommends applying the trephine to the upper and lower parts of the cavity, and then cutting away the intervening portion of bone with the saw or gouge. But there can be no doubt, that a more prudent way would be to go on with the enlargement of the aperture in the bone, at the place where the first perforation took place, if the sequestrum presented itself equally well there; because, by proceeding in this manner, the surgeon might discover that the dead fragment could be taken out without so great a destruction of bone as is caused in the other mode; and if this were not to be the case, no harm is done, as the necessary removal of bone can be continued.

When the bone which includes the sequestrum is a new production, and the operation is not too long deferred, the soft state of the bone will enable the operator to perform the needful excisions with the bistoury alone.

When the sides of the cavity in the original bone are thin, fragile, and pierced with numerous holes, the surgeon can break away a sufficient portion with a pair of forceps.

When several sinuses exist in the bone, each may be dilated, in the manner which seems most advantageous.

Sufficient openings having been made into the cavities including the sequestra, the next object is to extract these dead portions of bone. In accomplishing this part of the operation, Weidmann particularly advises two things: first, that no piece of the sequestrum be left behind; secondly, that no injury be done to the membrane which lines the cavity in which the dead bone is lodged.

This author observes, that there are examples, in which the vicinity of certain parts impedes the surgeon from making an opening in the bone large enough for the extraction of a voluminous sequestrum in an entire state. In this circumstance, he recommends the sequestrum to be broken into pieces by any convenient means, and the fragments to be separately removed.

Weidmann has recorded an extremely interesting case, to prove how much may sometimes be effected by taking away the sequestrum. A man, 34 years of age, who had an internal necrosis of the tibia, with abscesses and œdema of the whole limb, and who was reduced to the lowest ebb of weakness, was put under this excellent surgeon's care. A perforation was made with a trephine in the upper head of the tibia; but

this opening not proving ample enough, it was enlarged with a small saw, and a gouge and mallet. The sequestrum was then extracted. The patient's state afterward gradually improved, and in nine months he was completely well.

It is not to be dissembled, however, that cases do exist, in which amputation affords the only chance of saving the patient's life. In fact, it sometimes happens, that the cavities, in which the sequestra are contained, communicate with those of the neighbouring joints, which then become filled with matter, and caries attacks parts of the bones, to which the necrosis does not extend. On some occasions, the dead pieces of bone are very numerous, and each has a separate cavity; while, in other instances, the sequestra lie so deeply, that a passage for their extraction cannot be prudently attempted. Sometimes, also, a necrosis is complicated with another disease in its vicinity. Lastly, such may be the reduced state of the patient's health, and the particular condition of the necrosis itself, that the constitution cannot hold out during the whole time which would be requisite for the detachment of the sequestrum. Under circumstances like these, amputation is necessary, and ought not to be delayed.

NEPHROTOMY. (From *νεφρὸς*, a kidney; and *τέμνω*, to cut.) The operation of cutting a stone out of the kidney; a proceeding which, perhaps, has never been actually put in practice. In the *Abrégé Chronologique de l'Histoire de France, par Mézerai,* and in the *Phil. Trans. for* 1696, two cases of what is called nephrotomy are mentioned; but several circumstances in the accounts led Haller and others to conclude, that the operation alluded to in the first work was nothing more than the high operation for the stone. With respect to the example in the latter work, the particulars are not detailed enough to prove that an incision was really made into the kidney. There is no doubt that stones have often been extracted from abscesses about the region of the kidney, after being touched with a probe. But with regard to cutting into the kidney, the deep situation of this viscus, and the want of symptoms, by which the lodgement of a stone in it can be certainly discovered, will always be strong objections to the practice. When a stone, from its size, cannot pass from the kidney, and excites inflammation and suppuration, no doubt, the surgeon may make an incision into the tumour, and extract the calculus. In this sense, nephrotomy is certainly a practicable operation. Warner contends, that it can only be practised in such circumstances, notwithstanding whatever may have been said by Marchetti, or others, upon the subject. In such a case, the operation would not be attended with any greater difficulty, than the opening an abscess in any other part of the body.—(See *Warner's Cases in Surgery, p.* 241, *edit.* 4.)

NITRIC and NITROUS ACIDS. As these are medicines of considerable importance in surgery, they claim particular notice. Nitrous acid is a yellow or orange-coloured fluid, emitting, when exposed to the air, deep orange-coloured, extremely suffocating fumes. It consists of nitrous gas, loosely combined with nitric acid and water; and the colour varies according to the proportion of nitrous gas which is present.

Nitric acid is a colourless, or very pale yellow, limpid fluid, emitting, when exposed to the air, white suffocating vapours. It is highly corrosive, and tinges the skin yellow, the tint remaining till the epidermis peels off. The constituents of nitric acid, independent of the water which gives it the fluid form, are 25.97 azote, and 74.03 oxygen in 100 parts.—(See *Thomson's Dispensatory, p.* 438, 439, *ed.* 2.)

Both these acids in a diluted state have been extensively tried, as a substitute for quicksilver, in the cure of lues venerea; and really, upon looking over the mass of evidence brought forward in proof of the power which they seem to possess over this disease, it is at first difficult to entertain the slightest doubt of their efficacy. The cases adduced are numerous, some of them minutely detailed; the gentlemen who have published them men of reputation and abilities; and (what especially claims attention) these examples of successful treatment are generally allowed to have been syphilitic, or, at all events, complaints, the differences of which from the venereal disease have not been, and could not be, specified. Whoever impartially considers the immense body of facts published by Dr. Rollo, Mr. Cruickshank, Dr. Beddoes, Dr. P. G. Prioleau, of Charleston, South Carolina, and others, exemplifying the success with which the venereal disease may be treated by the nitrous or nitric acid, must be surprised to find, that the accounts delivered by these gentlemen by no means correspond to those of some other eminent practitioners. How to reconcile these seemingly discordant statements, whether by supposing some undefined differences in the nature of the cases adduced, or some variation in the goodness of the medicine itself, is indeed perplexing. Nor is a solution of the question at all facilitated by the results of later investigations, tending to prove the general curability of syphilis without mercury or any medicine whatever; because, if we admit this as a fact, the circumstance of a considerable proportion of cases not yielding or being radically cured when the nitric and nitrous acids are exhibited, as asserted by Mr. Pearson and others, would argue, that giving such acids is worse than leaving the disease entirely to itself. The more I reflect upon all that we know about the venereal disease, however, the more I am inclined to adopt the sentiment, that it is not one disorder, but probably many, which go under this name, their exact shades of difference not having yet been detected nor described. If this supposition be admissible, the contradictory statements given by various authors about what their experience has taught them of this or that mode of treating the disease, may all be immediately reconciled.

The practice of exhibiting nitric acid, in lieu of quicksilver, began with Mr. Wm. Scott, a surgeon at Bombay, who is said to have been led to the experiment by a suggestion thrown out by Girtanner, that the efficacy of the various preparations of quicksilver probably depended upon the quantity of oxygen combined with them.—(*Grens. Journ. de Physick. b.* 3, *p.* 31, 1790.) In August, 1793, Mr. Scott being himself afflicted with chronic hepatitis, resolved to take a quantity of oxygen, united to some substance for which it has no great attraction; and after some reflection, nothing appeared to him better than nitric acid. September 11th he took at different times about a drachm of the strong nitric acid diluted with water. Soon after drinking it he felt a sense of warmth in his stomach and chest; but no disagreeable sensation nor any other material effect. The two following days the medicine was continued, the gums beginning to be somewhat red and enlarged. He slept ill; but could lie for a length of time on his left side, which the disease of the liver had prevented him from doing during many months previous to this period. He also felt a pain in the back of his head, resembling what he had commonly experienced when taking mercury. On the fourth day his gums were a little tender; the headache and pain about his jaws still troubled him; but the symptoms of his liver-complaint had already left him. The acid was continued on the 4th, 5th, and 6th days: the soreness of the mouth increasing, and a salivation taking place. On the 7th day he felt his mouth so troublesome that he took no more acid. His mouth got gradually well, and he found his health considerably improved.

Mr. Scott likewise administered the nitric acid in several cases of tedious intermittents, in two cases of diabetes, and in many syphilitic cases, with the happiest effect. His account of the nitrous acid was first published in the Bombay Courier of April 30th, 1796, and soon afterward republished in this country.—(See "*An Account of the Effects of the Nitrous Acid on the Human Body*," *by W. Scott, in Duncan's Annals of Medicine for* 1796, *vol.* 1, *p.* 375—383.) The hypothesis suggested by Girtanner in 1790, that the efficacy of mercury in the treatment of the venereal disease depended upon the oxygen combined with this mineral, required but little extension to lend to the discovery of the antisyphilitic virtues of the acids. Yet Girtanner had all his attention so fixed on mercury, that it never struck him that the principle on which he explained the efficacy of this medicine might apply to other substances which abound with oxygen, and are readily separable from it. This was the idea which made Mr. Wm. Scott begin to suspect, that the nitric acid might be as efficacious as mercury in venereal cases; and as he had already observed a great analogy between the effects of this acid and mercury in the experiments which he made with the first of these medicines in his own case of chronic hepatitis and other diseases, he ventured to recommend the trial of it in syphilis. The result was, that the acid was found not only to equal the preparations of mercury, but sometimes to surpass them; for it had the best effect in some cases where mercury had been tried in vain, and it was observed to remove the disease in less time than the common remedy. Nor were any of the inconveniences, usually known under the names of *mercurial symptoms*, *mercurial fever*, found to be the consequence of its employment however long continued. With it alone many syphilitic cases are stated to have been cured, the disease not having returned at the end of two years.—(See *Duncan's Annals of Medicine, &c. vol.* 1, 1796, *p* 383, *&c.*)

The letter from Mr. Scott to Sir Joseph Banks, describing these effects of the nitric acid in India, soon excited the attention of medical practitioners both in Europe and America, the inquiry being taken up with all the zeal which the preceding accounts were calculated to inspire. In 1797, Mr. G. Kellie, a surgeon of the navy, gave the nitric acid to five sailors, affected with gonorrhœa, venereal sores, and buboes. Three of them were perfectly cured. A fourth, who had sores on the glans, and who had been much debilitated by the long use of mercury, recovered nearly his original strength while taking the acid; but the sores were not healed before mercury had been repeatedly exhibited. In the fifth patient, who was also scrofulous, the nitric acid contributed very essentially to heal the sores. On the whole, Mr. Kellie seems to regard this medicine as possessing very efficient power of stopping and eradicating the venereal disease.—(See *Letters from G. Kellie, respecting the Effects of Nitrous Acid in the Cure of Syphilis, Duncan's Annals of Medicine for* 1797, *p.* 254. 277.)

In the same year appeared a letter, in a German periodical work (*Hufeland's Journ. der Prakt. Heilk. bd.* 4, *p.* 356—359), written by Albers, giving the history of a venereal ulcer on the breast, successfully treated by the nitric acid.

The reports of Dr. Prioleau, who tried the nitric acid in the autumn of 1797, are particularly favourable to the practice. "We have seen (says he) every stage and form of syphilis cured by this medicine, and even in habits broken down by the antecedent use of mercury, under which the disorder had gained ground. The patients recovered their health and strength in a short time, without the use of diet-drinks, bark, or any other tonic medicine whatever."—(See *Caldwell's Medical Theses, p.* 103, 8*vo. Philadelphia*, 1805.)

The praise of the nitric acid from numerous quarters induced Dr. Rollo to try it in the military hospital at Woolwich, and in conjunction with Mr. Cruickshank to examine farther into the antisyphilitic virtues of oxygenated substances. The results of Mr. Cruickshank's investigations constitute the second part of Rollo's work on diabetes, published in 1797. The me

dicines, which were selected for the experiments, were the nitric, citric, and muriatic acids, and oxygenated muriate of potash. Of these, the nitric acid and the oxygenated muriate of potash were found to possess the greatest efficacy: the first acting in many cases with remarkable mildness; the second, with greater expedition and certainty. The new plan was tried upon young persons affected with primary venereal complaints, who had never used mercury; and no other internal medicine was given except opium when required for diarrhœa or colic. The liquor plumbi acetatis dilutus was used as a wash for chancres. In debilitated subjects, sure and speedy good effects were observed uniformly to follow; and hence, previously to giving the acid to strong, plethoric patients, the method of preparing them for this treatment by purging and bleeding was adopted, as is alleged, with great success. In some cases, after the nitric acid had been continued a good while without producing a salivation, the exhibition of mercury for a short time completed the cure. Mr. Cruickshank's opinion in favour of the new remedies was on the whole extremely sanguine, as he ventures to express his conviction, that they would render the employment of mercury in the cure of the venereal disease unnecessary.—(See *An Account of two Cases of Diabetes Mellitus, with Remarks, &c. by John Rollo, M.D. vol.* 2, 8*vo. Lond.* 1797.)

In the same year Dr. Beddoes published a valuable work, comprising all the information which had then transpired respecting the antisyphilitic virtues of the nitric acid, with additional communications from his medical friends.—(See *Reports principally concerning the Effects of Nitrous Acid in the Venereal Disease, by Thom. Beddoes, Bristol*, 1797.) And two years afterward the same author finished a still more comprehensive volume on the subject.—(*A Collection of Testimonies respecting the Treatment of the Venereal Disease by Nitrous Acid, Lond.* 1799.)

From the preceding work we learn, that in the Plymouth Hospital Mr. Hammick gave the nitric acid to between sixty and seventy venereal patients, and that the cures were generally more speedily accomplished than with mercury, no ill effects being produced on the system similar to those usually remaining after the use of the latter mineral. He assures us, that after the removal of the symptoms, the disease never returned; and that for debilitated, scorbutic, or scrofulous patients, affected with venereal complaints, the acid was found a most valuable means of relief.

Dr. Geach of the same hospital is also stated to have employed the nitric acid with such effect that he rarely had occasion for mercury; the livid colour of the countenance, sordid fetid excoriations of the scrotum, and other symptoms, which had long resisted the latter mineral, all quickly giving way to the new medicine. Another practitioner of the name of Giedlestone, however, had not equal success in his experiments; for, in several cases, the acid did not bring about a cure, and after being continued eight or ten days, and inducing a salivation, it even rendered the condition of some patients worse. On the other hand, Mr. Sandford, a surgeon at Worcester, found the acid a very useful and effectual medicine in venereal cases, where mercurials had been long exhibited in vain. The trials of the nitric acid, made by Professor Rutherford at Edinburgh, had various results; the medicine sometimes proving completely ineffectual, and in other instances appearing to be a perfect antidote for the worst syphilitic complaints.

Dr. Beddoes concludes with some observations in answer to Mr. Blair, who had become averse to the new notice.

In 1798, Dr. Ferriar published some remarks on the nitrous acid.—(See *Medical Histories and Reflections, vol.* 3, *p.* 280—310.) He tried this medicine in various ways, either alone, or after or in conjunction with the exhibition of mercury. His inferences are, that in the treatment of the venereal disease, the nitrous acid is useful only in protracted cases. He corroborates, however, the generally received opinion, that where the patient has been considerably reduced by the long or injudicious employment of mercury, the nitrous acid is a most beneficial medicine.

In this year, Mr Blair wrote some observations on the venereal disease, and the new method of treating it.—(*Essays on the Venereal Disease and its concomitant Affections, Lond.* 1797.) In this work, the new remedies are generally condemned as ineffectual; and hence originated a paper war between this writer and Dr. Beddoes, "literarium certamen, non sine bile gestum," as Dr. Hoist has expressed it.—(*De Acidi Nitrici Usu Medico, p.* 73, 8*vo. Christianæ*, 1816.) In this controversy numerous other practitioners readily joined, as for instance, Macartney, Rowley, Philips, Hooper, Lidderdale, &c., all of whom adduced cases in proof of the frequent inefficacy of nitrous acid; and these were collected and published by Mr. Blair, who, suspecting the cases of failure with this medicine to be more numerous than those of success, considers himself unjustified in regarding it as an antisyphilitic to be depended upon. At the same time, he bears testimony to the virtues of the acids, exhibited in venereal cases either singly or alternately with mercury where the patient's strength had been much reduced; and he confesses that venereal buboes, indurated glands, nocturnal pains in the bones, and gonorrhœa yielded to these remedies.

Seven years after the appearance of Mr. Blair's work, Mr. Pearson delivered his sentiments in a book of considerable merit.—(*Obs. on the Effects of various Articles of the Materia Medica in the cure of Lues Venerea, 2d ed. Lond.* 1807, *p.* 198, *&c.*) He relates a very few examples, in which the nitrous acid appeared effectual in curing chancres, and one of its virtues in gonorrhœa; the only one which this gentleman had ever seen. The rest of his observations are unfavourable to the character of the medicine as an antisyphilitic meriting confidence. The first trials which Mr. Pearson made, were of the nitric acid; but as he did not remark any of its effects to be different from those produced by the nitrous acid, he commonly employed the latter in the following form:—Nitrous acid, two drachms; pure water, a pint and a half; syrup, four ounces. This mixture was usually taken in the space of twenty-four hours. As local applications, he employed a saturnine lotion to the sores, and emollient poultices to tumours and inflamed parts. All mercurial applications were absolutely prohibited.—(*P.* 200.) In making his inferences in a subsequent page, he says, "The nitric and nitrous acids have removed both primary and secondary symptoms of syphilis; and in some instances it seems that the former have not recurred, nor have secondary symptoms appeared at the period they commonly show themselves, when the cure has been imperfect. But as far as my own experience extends, and that of many respectable friends, who are connected with large hospitals, a permanent cure has never been accomplished by these acids, where secondary symptoms have been present. The same acids, when exhibited with the utmost care and attention to many patients, labouring under the primary symptoms of the venereal disease, and where they have agreed perfectly well with the stomach, have been nevertheless found inadequate to the cure of those symptoms. Indeed, the failures which have occurred, both in my own practice and that of many of my surgical friends, have been so numerous, that I do not think it eligible to rely on the nitrous acid in the treatment of any one form of the lues venerea." However, Mr. Pearson joins several other writers in bearing witness to the good effects of this medicine, where impairment of the constitution renders the employment of mercury inconvenient or improper. Here, he says, it will restrain the progress of the disease, and improve the health and strength. On some occasions, he thinks that it may be given in conjunction with a course of mercurial inunction; and he agrees with other practitioners about its supporting the tone of the stomach, acting as a diuretic, and counteracting the effects of mercury on the mouth and fauces.—(*P.* 236—238.)

While these inquires were going on in England, numerous experiments on the same subject were undertaken in France. In a work published in 1797, Alyon positively declares that mercury ought to be entirely relinquished in the cure of the venereal disease.—(*Essai sur les Propriétés Médecinales de l'Oxygène, et sur l'Application de ce Principe dans les Maladies vénériennes psoriques, et dartreuses; Paris, an* 5, 8*vo.* Here we find a relation of many cases successfully treated in the hospitals of Val-de-Grace and St. Dennis, by the oxygenated muriate of potash, the nitric, oxymuriatic, and citric acids, an ointment of the author's own invention, called the unguentum oxygenatum, being applied to the sores.—(See *Unguentum.*) In a second edition of the above book, which came out in

1799, the same doctrine and practice are corroborated by farther observations.

In 1798, Dr. Swediaur brought out the third edition of his treatise on the venereal disease (*Traité Complet sur les Symptômes, les Effets, la Nature, et le Traitement des Maladies Syphilitiques*), in which he highly commended the virtues of the nitrous acid, and oxygenated acid, as expediting the cure with very few exceptions. But in the fourth edition he retracts, and details the results of the new practice, as tried upon twenty-six venereal patients in the *Hospice d'Humanité:* of these only seven cases remained permanently cured; the issue of seven others was doubtful; and in twelve, no amendment was observed.

Nor were the statements of Lagneau much more favourable to the reputation of the nitrous acid as an antisyphilitic; for, from the trials which he had seen made of it, he concluded that it was not unfrequently ineffectual, while it was apt to excite an obstinate cough and hæmoptysis.—(*Exposé des Symptômes de la Maladie Vénérienne, des diverses Méthodes de Traitement, &c. 3me éd. Paris*, 1812.)

The reports of Dr. Odier, of Geneva, however, were rather more propitious; as he says the nitrous acid increases the efficacy of mercury, and lessens or removes the inconveniences arising from its unskilful administration. But he candidly acknowledges, that his experience had not been great enough to enable him to pronounce what degree of confidence ought to be put in the acid as a remedy for syphilis.—(*Man. de Méd. Pratique; Génève, p.* 249.)

The practice of exhibiting the nitric acid for the cure of syphilitic affections was not tried in Germany so soon as in England and France. Albers, however, in 1797, gave an account of Scott's successful experiments, and of the efficacy which they evinced in some cases seen by that gentleman in the Infirmary at Edinburgh (*Hufeland, Journ. d. Prakt. Heilk. vol.* 20, *p.* 68); while Behn, who had visited Paris in the winters of 1797 and 1798, briefly noticed the various results of the trials which he had seen made of this acid, in the "Clinique de Perfectionnement," for the cure of obstinate syphilitic cases.—(*Erinnerungen an Paris, zunächst für Aerzte geschrieben von G. H. Behn Erst. Heft. Berl.* 1799, *p.* 110.) At length, in 1799, Struve, who translated Mr. Blair's first publication into German, communicated to the profession the particulars of some experiments made by himself with the acid: he declares, that he had very often found it an excellent remedy for inveterate pains in the bones and derangement of the constitution, produced either by the syphilitic virus, or the injudicious employment of mercury. However, in common cases, mercury is represented as the best antisyphilitic medicine.

Afterward Professor Würzer was induced to try the nitrous acid in a case that had resisted mercury for six months; the patient having got rid of some chancres and a sore throat, but being left with violent nocturnal pains, blotches and sores all over his body, and in a very reduced condition, without the least appetite. Here, in 27 days, the acid, together with sarsaparilla and the warm bath, not only removed all the complaints, but actually restored the patient's original strength and healthy appearance. In a short note annexed to this case, Hufeland gives it as his opinion, derived from experience, that the nitrous acid is effectual in obviating the sequelæ and anomalous diseases induced by lues venerea, but that it does not permanently cure the latter affection itself.—(*Etwas über die Heilkraft der Salpetersaüre in venerischen Krankheiten, Hufel. Journ. d. Prakt. Heilk. bd.* 8, *st.* 4, *p.* 139 143.)

These vague and endless contradictions induced Schmidt, an eminent professor at Vienna, to make a series of experiments with the nitric acid, for the purpose of ascertaining its power in cases of syphilis.—(See *Beobacht, der Kaiserl. Königl. Med. Chir. Josephs Academie zu Wien. bd.* 1, *Wien*, 1807, *p.* 147—189.) Under his directions, the acid was given in the winter of 1799 to five soldiers affected with the venereal disease in various degrees and forms. In every one of these cases, the medicine was found efficacious; but the degree of efficacy was remarked to vary considerably, according to the nature of the constitution, and the kind of local complaints. Thus, in robust patients, moderate doses of the acid soon produced benefit: while, in weak persons, disposed to scurvy or scrofula, a larger quantity of the medicine and more time were requisite. This assertion we see is exactly the reverse of what appeared to happen in the cases treated by Mr. Cruickshank. However, professor Schmidt entertains strong doubts whether the nitric acid is adequate to the cure of all the forms of syphilis; and he thinks that neither this nor any similar medicines will ever supersede the necessity for mercury.

Ontyd, a Dutch practitioner, approves of the use of the nitric acid, with some limitation: while he admits its efficacy in removing local symptoms, he is strongly against its employment in cases of confirmed lues. The latter assertion, I conceive, is exactly contrary to the results of modern experience, most of these protracted bad cases being those which are particularly benefited by this acid.—(*Nieuwe scheidekundige Bibl. te Amsterdam; by Doll*, 6*de st.* 1799, *p.* 166.) The tracts of Boetticher (*Bemerk. über Medicinal-verfass. Hospit. u. Curarten*, 2*tes Hefr. Königsb.* 1800, 8.), of Ritter (*Erfahr über die innerl u. äusserl. Anwendung d. Salpeters. Hufel. Journ. b.* 10, *st.* 3, *p.* 191—197), and of Frankenfeld (*Hufeland'e Journ. der Prakt. Heilk. bd.* 22, *st.* 4, *p.* 96—98), need only be specified here, as decidedly unfavourable to the character of the nitrous acid, as a remedy for syphilis.

Another German author, who has entered into the present inquiry, is F. A. Walch, whose statements are very unfavourable to the use of the nitrous acid, as he absolutely denies that it ever accomplishes a lasting cure.—(*Ausführl. Darstell. d. Urspr. &c. d. Venerisch. Krankh. Jena*, 1811, *p.* 197, 198.)

In a periodical work, mention is made of one case, which, after resisting a long course of mercury, and also the nitric acid, was ultimately cured by restricting the patient for a few weeks to a very reduced diet.—(*Hufel. Journ. d. Prakt. Heilk. bd.* 34, *st.* 2, *p.* 56.)

For much of the foregoing historical account, I am indebted to Holst, *Diss. de Acidi Nitrici Usu Medico*, 8*vo. Christ.* 1816; in which an explanation of the results of farther trials of the medicine in Denmark and Sweden may be perused. From these countries the reports are mostly less favourable to the reputation of the medicine, than the accounts already delivered.

According to Holst, the following are the chief circumstances under which the employment of nitrous or nitric acid is generally sanctioned.

1. Where the disease is complicated with scurvy.

2. Where it is attended with scrofulous enlargement of the glands, and other strumous symptoms. I may remark, however, that these complaints are often as undefinable, as some of the forms of syphilis, and therefore the rule is frequently difficult of application.

3. Where the disease is accompanied with considerable debility, either brought on by mercury or febrile indisposition.

4. Where, from idiosyncrasy, mercury cannot be safely exhibited. Experience fully proves that there are some patients, more especially females, in whom a few grains of mercury taken inwardly, or mercurial frictions on the most limited scale, bring on vomiting, rheumatic pains, nervous febrile symptoms, colic, spasms, severe headache, and a rapid immoderate salivation.

5. Several practitioners forbid the use of mercury during the latter months of pregnancy.—(*Bangii, Prax Med. Hafn.* 1789, *p.* 570; *Swediaur; Aronsonn Vollst. Abhdl. aller Ven Krkht. Berlin*, 1811, *p.* 211.) Holst observes that the reason of this advice is not stated, though no doubt it must proceed from an apprehension of mercury exciting a miscarriage.

Mr. Pearson's mode of exhibiting the nitrous acid has been already mentioned. Some practitioners give it as follows: ℞. Gum. arab. ℥ iv. aquæ menth. ℥ viij. acid. nitrosi, vel nitrici ℥ ij. ℥ iij. F. M. Of this mixture, a table spoonful is to be taken every hour, mixed with some sweetened water. Should the acid occasion colic or diarrhœa, its quantity must be lessened, and opium added to the mixture.

As the nitrous and nitric acids decompose and destroy the teeth, the utmost care must be taken to prevent so serious an effect. Their being properly diluted, and blended with sugar, syrup, or mucilage, will materially tend to hinder the evil. But the safest way is always to drink the mixture through a glass tube, and wash the mouth well immediately after every dose.

Strong nitrous acid, extricated in the form of vapour, is often employed as a means of purifying the air of large crowded hospitals and sick rooms; a subject on which the observations of Dr. J. C. Smyth and G. de Morveau are particularly interesting. The nitrous acid is sometimes taken by accident, or design, as a poison. Here, according to the observations of Tartra, Orfila, &c., the best antidote is calcined magnesia or soap. If the first of these articles be at hand, a drachm of it, suspended in a glass of water, is to be instantly given, followed by copious draughts of some mucilaginous drink, the design of which is to fill the stomach and excite it to reject the diluted poison. While the vomiting is going on, the doses of magnesia are to be repeated, and followed as in the first instance by draughts of linseed-tea, solution of gum arabic, milk, or broth.

The nitrous acid has also been extensively tried as a means of curing syphilitic complaints, in the form of what is termed the *nitro-muriatic bath*, of which a description will be given in speaking of the *Venereal Disease*.

When reiterated courses of mercury induce dropsy, as not unfrequently happens in very impaired constitutions, Mr. Carmichael prescribes the nitrous acid in as large doses as the stomach will bear, conjoined with digitalis.—(*Essays on Venereal Diseases, &c.*) Taken in doses of eight, ten, or fifteen drops, two or three times a day, it is alleged to be efficacious in the cure of some eruptive complaints, especially of the lower extremities, connected with disorder of the liver.—(*Wilson's Pharm. Chir. p.* 6.) Another well-informed writer also bears testimony to its good effects when used together with mercury for old obstinate ulcerations of the legs, though no venereal taint can be suspected; and, he says, it may be applied with benefit as a local stimulant to fetid ulcers, attended with a thin ichorous discharge, and in some examples of caries. In such cases, ℥ij. of the diluted acid is to be mixed with ℥j. of water.—(See *A. T. Thomson's Dispensatory, p.* 441, *ed.* 2.) With respect to caries in the sense of *necrosis*, however, the reader will understand from what is said in the article on the subject, that it can rarely be advisable to apply this or any other acid, either to the exfoliating portion of bone, or to that which is yet alive. The nitrous acid has sometimes been used for destroying warts, condylomata, and other excrescences; and the nitric acid, applied to the skin, has been proposed as a means of producing an immediate vesication of the part. By Sir E. Home, it is praised as a local application for certain ulcers when properly diluted.—(See *Ulcers.*) It is likewise commended by some writers as a very useful local application in cases of hospital gangrene: and an interesting paper was lately published by Mr. R. Welbank, detailing the excellent effects of the undiluted nitric acid, as an application to diseases, which he has described under the name of sloughing phagedena, and which he considers as identical with hospital gangrene.—(See *Med. Chir. Trans. vol.* 11, *p.* 369, *and Hospital Gangrene.*) The cases reported by this gentleman, are highly favourable to the practice, which, as may be seen by reference to the article *Hospital Gangrene*, is not entirely new with respect to this disease; and in speaking of *mortification*, I have mentioned that it was Dr. Kirkland's practice sometimes even to dress certain sloughing diseases with a solution of mercury in nitrous acid. But notwithstanding these facts, and the well-known custom of Sir A. Cooper to apply to sloughing phagedenic ulcers the nitric acid lotion, composed of 50 drops of the acid, and a pint of distilled water, I feel that Mr. Welbank has rendered a service to the profession by drawing their attention still more particularly to the use of undiluted nitric acid in the forms of phagedena, which he has so well described.

NITRO-MURIATIC BATH.—(See *Venereal Disease.*)

NODE. A swelling of a bone, or a thickening of the periosteum from a venereal cause.—(See *Exostosis* and *Venereal Disease.*)

NOLI ME TANGERE. A species of *lupus*, under which term Dr. Willan intended to comprise, together with the *noli me tangere* affecting the nose and lips, other slow tubercular affections, especially about the face, commonly ending in ragged ulcerations of the cheeks, forehead, eyelids, and lips, and sometimes occurring in other parts of the body, where they gradually destroy the skin and muscular parts to a considerable depth.—(*Bateman's Synopsis of Cutaneous Diseases, p.* 296, *ed.* 3.)

Sir E. Home says, that the ulcers for which he has been led to employ arsenic, are named, from the virulence of their disposition, *noli me tangere*, and are very nearly allied to cancer; differing from it in not contaminating the neighbouring parts by absorption, but only spreading by immediate contact. Ulcers of this kind differ exceedingly from one another in their degree of virulence; but they are all so far of the same nature, that arsenic in general agrees with them, and puts a stop to their progress, while they are aggravated by milder dressings.—(*Home on Ulcers, ed.* 2, *p.* 267.)

The disease generally commences with small tubercles, which change after a time into superficial spreading ulcerations on the alæ of the nose, more or less concealed beneath furfuraceous scabs. Sir A. Cooper believes, that the disease consists in ulceration of the sebaceous glands, or follicles of the nose. The cartilages and even the whole nose are frequently destroyed by the progressive ravages of this peculiar disorder, which sometimes cannot be stopped or retarded by any treatment, external or internal.

The specific ulcerations do not generally extend to the parts far within the nostrils; but at the time that I am writing this article, there is in St. Bartholomew's Hospital a curious example, in which the greatest part of the nose is destroyed, and the ulceration proceeds even through the front part of the palate into the mouth. The morbid process sometimes stops for a considerable time, and then is renewed with increased violence. The following case illustrates the nature of *noli me tangere*, and one mode of treatment to which it yielded. Jane Chatillon, 45 years of age, was attacked in the course of September, 1788, with an inflammation on the left ala of the nose. Some time afterward the part ulcerated, which occasioned a troublesome and sometimes a painful itching: different means were unsuccessfully employed, and the case remained nearly in the same situation until the month of September in the following year. At this period, the ulcer spread very fast; the septum nasi, the muscles, and cartilages of both sides were in a short space of time destroyed. The ulceration extended on the left side, along the loose edge of the upper lip. This was the state of her case on her admission into the Hospital of St. Louis, in the month of October, 1789.

A poultice moistened with aq. veg. was applied twice a day to the ulcer; a sudorific ptisan prescribed; and a pill, composed of one grain of calomel, and one grain of sulph. aurat. antimonii, ordered to be taken every day. From the fifth day the inflammation lessened. No other sensible alteration took place till the 21st. The suppuration, which till this time had been black and putrid, now became white and inodorous

On the 37th the discharge was trifling, and the part was dressed with pledgets, dipped in a solution of verdigris and corrosive sublimate, in the proportion of six grains of each to a pint of water. On the 40th day, cicatrization began to take place, and was finished by the 60th.

Some time before the disease was completely cicatrized, an issue was made in the arm, which was healed up, without any inconvenience to the patient, six months after the cure.—(*Parisian Chirurgical Journal, vol.* 1.)

One of the best external applications to *noli me tangere* is the following lotion: ℞. potassæ arseniatis, gr. iv. Aq. menthæ sativæ, ℥iv. Spiritus vini tenuioris, ℥j. Misce et cola. I have seen several cases in St. Bartholomew's Hospital, which were either cured or seemed disposed to get well with this useful application. The solution of arsenic which Sir E. Home has always used, is made by boiling white arsenic in water for several hours, in a sand heat. When given internally, the dose is from three to ten drops; when for external application, a drachm is to be diluted with ℔ij. of water; and this solution is gradually made stronger as the parts become accustomed to it, till it is of double strength. However, this mode of using arsenic is by no means a well-regulated one; and Plunket's caustic (see *Arsenic*) for outward employment is not nearly so neat an application as the above-mentioned lotion. Sir A. Cooper applies the following ointment: ℞. Arsen. oxydi sulph. flor. ℥ß ℥j. Ung. cetacei ℥ij. M. In 24 hours it produces a slough, which, being covered

with any simple dressing, separates, and the part then frequently heals.—(See *Lancet, vol.* 1, *p.* 264.) At St. Bartholomew's Hospital, arsenic is administered internally in the following formula: ℞. Potassæ arseniatis gr. ij. Aquæ menthæ sativæ ℥iv. Spiritus vin. ten. ℥j. Misce et cola. Dosis ℥ij. ter quotidie. In this way, the quantity of arsenic is nicely determined. The generality of practitioners prescribe the liquor arsenicalis of the London Pharmacopœia; a formula that is nearly the same as that recommended by Dr. Fowler, and very convenient. One scruple of the argentum nitratum, dissolved in half an ounce of distilled water, makes a very good application, which, although generally inferior in point of efficacy to arsenical ones in the present disease, occasionally does good when nothing else seems to produce any benefit. The above case makes us acquainted with another lotion which deserves farther trial. All fluid remedies must be applied to the part by dipping little bits of lint in them, placing these on the ulcerations, and covering the whole with a pledget.

The ointments which seem most likely to prove useful applications to *noli me tangere* are, the unguentum hydrargyri nitrati, the unguentum picis, and unguentum sulphuris. As far as my experience extends, they are generally less efficacious than lotions in the present cases; but in particular instances, they prove superiorly useful: and it deserves especial notice, that surgeons can often make no progress against this inveterate disease, unless they apply a different sort of dressing every day; sometimes a lotion, at other times an ointment. The little ulcers may occasionally be touched with the argentum nitratum, or a strong solution of it. The small furfuraceous scabs which are continually forming on the part affected, should be softened with a little of the unguentum spermatis ceti, and removed with as much tenderness as possible.

We have already remarked that arsenic is a good medicine to be given internally, and the best mode of exhibiting it has been already explained. Another medicine which is often useful in these cases, is what is known by the name of Plummer's pill, or the compound calomel pill. ℞. Hydrargyri submuriatis, sulphuris antimonii præcipitati singulorum, gr. xii. Guaiaci gummi resinæ, gr. xxiv. Saponis quod satis sit. Misce; fiant pilulæ duodecim. Dosis una bis quotidie.—In other instances, we may try the decoctum ulmi or sarsaparillæ, with one of the following pills thrice a day: ℞. Hydrargyri submuriatis gr. vj. Succi spissati cicutæ ℥j. Misce; fiant pilulæ duodecim. The hydrargyrus sulphuratus has occasionally been given as an alterative medicine, for the relief of *noli me tangere;* with what good effect I cannot pretend to say.

In three or four less severe cases of lupous tubercles on the face, which had made no progress towards ulceration, Dr. Bateman saw the solution of muriate of barytes, taken internally, materially amend the complaint. Sometimes, also, a separation of the diseased parts from the sound has been effected with the knife, or caustic, and the progress of the complaint been stopped. —(*Synopsis of Cutaneous Diseases, p.* 296, *edit.* 3.)

NYCTALOPIA. (From νὺξ, night; and ἄψ, the eye, or ὄπτω, to see.) An affection of the sight, in which the patient is blind in the daylight, but sees very well at night.

Nyctalopia, *visus nocturnus*, or day-blindness, vulgarly called owl-sight (says M. Lassus), is an affection in which the patient either cannot see at all, or sees but very feebly, objects which are in the open daylight, or situations where there is a strong light; but discerns them very well when they are in a darkish place, or at sunset, or in the night-time, if not immoderately dark. —(See *Pathologie Chir. t.* 2, *p.* 539, 540.)

The Greek physicians are divided in their opinions concerning the now uncommon disease nyctalopia. Hippocrates expressly says, "we call those nyctalopes who see by night." The author of *Defin. Medic.* states, "that they see nothing in the daytime, but have their sight by night." On the contrary, Paulus Ægineta and Actuarius are as explicit in asserting that their sight is perfect in the daytime, but that they are blind by night. Ætius is of the same mind, though he is thought to favour the contrary opinion, when he says, "they see better by night than in the day, and if the moon shines they are blind." The author of Isagoge embraces both opinions, when he says, "they call those nyctalopes who, in the daytime, see more obscurely, at the setting of the sun more clearly, but when it is night much better; or, on the contrary, by day they see a little, but in the evening, or at night, they are blind." Galen explains the word by a night-blindness. Pliny, Varro, Nonius, Festus, Celsus, and other writers, give equally opposite definitions of the disorder. Dr. Pye questions whether these two descriptions of nyctalopia, so diametrically opposite to each other, may not be reconciled by considering the disorder as an intermittent one. The difference then will only consist in the different times of the approach of the disease; that of Hippocrates came on in the morning; that of Ægineta in the evening; both were expressly periodical, and the distance of time between the paroxysms in both was respectively the same; a whole day or a whole night. The various shape in which intermittents appear, very much favour, says Dr. Pye, such an opinion; and the apparent success of bark in the case which he has related, notwithstanding the unfavourable circumstances of the evacuations his patient laboured under, and the consequent necessity of its disuse, seem to confirm it in this gentleman's mind.—(*Med. Obs. and Inq. vol.* 1.)

In this work I shall follow Callisen, Richter, and the best modern surgical writers, in calling day-blindness *nyctalopia*, and night blindness *hemeralopia*.—(See *Callisen, Syst. Chir. Hodiernæ, vol.* 2, *p.* 392; and *Richter, Anfangsgr. der Wundarzn. b.* 3, *p.* 479.)

Nyctalopia, in the sense of day-blindness, is a very rare disease, in comparison with hemeralopia, which is a common disorder in warm climates. According to Dr. Hillary, there are persons in Siam, in the East Indies, and also in Africa, who are all of this cat-eyed species, or subject to the disease of being blind in the daytime and seeing well by night.—(*Med Univ. Hist. vol.* 7.) The same author notices the general rarity of the disorder, and mentions his having met with but two examples of it.

With respect to the causes of the complaint, Dr. Hillary observes, that it proceeds from too great a tenderness and sensibility of the iris and retina. M. Lassus thinks the causes may be of different kinds. "If, for instance (says he), there were a very small opacity, like a point, exactly opposite the pupil, or centre of the crystalline lens, the pupil contracting in the open daylight, would stop the entrance of the rays of light into the eye, and a day-blindness arise, which would be diminished by the expansion of the pupil in the shade. Here the cure would depend upon the removal of the opacity.

"Persons, whose pupils do not move freely, but remain much dilated, and do not sufficiently contract in light situations, are also affected with nyctalopia; for so large a quantity of the rays of light pass into their eyes, that it serves rather to destroy than assist vision. Such persons see tolerably well, and better than the preceding class of patients in a darkish place, and they ought to wear green spectacles in the daytime, in order to weaken the impressions of the rays of light. When a person is shut up a long while in a dark place, the pupils become habitually dilated, and if he exposes himself suddenly and incautiously to a strong light, the eyesight may be destroyed. There are other individuals, who, from excessive sensibility of the iris, cannot bear much light; their pupils instantly contract and close. This case (continues M. Lassus) may be brought on by too great indulgence in venereal pleasures, and in persons who have debilitated their constitutions during their youth." The same author mentions other cases, which seem to depend upon a species of irritability of the iris. In one instance an issue in the arm effected a cure, and he mentions the utility of blisters. He admits likewise, with Dr. Pye cases of intermittent or periodical nyctalopia, which begin regularly in the morning, and go off in the evening, the patient continuing blind whether he keep himself in a dark or a light place. The cause of these instances, which he observes are very uncommon, is generally seated in the primæ viæ, and requires emetics, resolvents, purgatives, and bark.—(See *Pathologie Chir. t.* 2, *p.* 540—542. Also *Richter Anfangsgr. der Wundarzn. b.* 5, *p.* 481.) In 1787, Baron Larrey met with a case of day-blindness in an old man, one of the galley-slaves at Brest, who had been shut up incessantly for thirty-three years in a subterraneous dungeon. His long residence in darkness had had such an effect on the organs of vision, that he could only see in the dark, and was completely blind in the daytime.—(See *Mém. de Chir. Militaire, t.* 1, *p.* 6.)

Nyctalopia may sometimes depend on a peculiarity in the structure and organization of the eye; by reason of which, the quantity of light, which only suffices for vision in an eye of natural formation, proves too abundant for a nyctalops, and absolutely prevents him from seeing at all. We know that in the eye there is a black substance, named the *pigmentum nigrum*; one supposed use of which is to absorb the redundant rays of light, which enter the pupil. A deficiency of it might perhaps account for a nyctalops being blinded with daylight, and seeing best at night.

For an account of nyctalopia, in the sense of night blindness, refer to *Hemeralopia*.

O

ŒDEMA. (From *οἰδέω* to swell.) A swelling arising from the effusion of a serous fluid in the cellular substance of a part; the affection, when more extensive, and accompanied with a general dropsical tendency receiving the name of *anasarca*. An œdematous part is usually cold and of a pale colour; and as it is little or not at all elastic, it *pits*, as surgeons express themselves, or, in other words, it retains for some time the impression of the finger, after being handled or pressed. Œdematous swellings are often connected with constitutional causes. In many cases, however, they seem to be entirely local affections, arising from such causes as only act upon the parts in which the disease is situated. Thus we observe that after violent sprains of the wrist or ankle-joint, the hands and feet often become œdematous: and limbs are frequently affected with œdema, in consequence of the return of blood through the veins being obstructed by the pressure of tumours on them, or that of splints, bandages, &c. Pregnant women are known to be particularly subject to œdema of the legs, owing to the pressure of the gravid uterus on the iliac veins. Persons who have been confined in bed, with fractured thighs or legs, generally have more or less œdema in their feet and ankles on first getting up again; and the affection in these cases is probably dependent on the loss of tone in the vessels of the limb.

In the treatment of œdema, great attention must always be paid to the nature of the cause, in order to determine whether the disease originate from a mere local or a general constitutional affection. When it depends on the pressure of a tumour on the veins, as we often see happen in cases of aneurisms, the effect cannot be got rid of till the cause is removed; and the aneurismal swelling must be lessened, before the œdematous one can admit of the same beneficial change. When œdema is the effect of vascular weakness in a limb, in consequence of sprains, contusions, &c. the best means of relief is to support the parts affected, with a laced stocking or a flannel roller, while they are also to be rubbed with liniments, and bathed with cold spring water, till they have perfectly recovered their tone.

With regard to the œdema attendant on the advanced stage of pregnancy, a complete cure cannot be expected till after delivery. The affection is generally more considerable in the afternoon than the morning, owing to the different effects of an erect and a recumbent position. Some relief may be obtained by the patient keeping as much as possible in a horizontal posture; and when great inconvenience and pain are felt, the parts may be fomented with any aromatic or spirituous application.

Frequently œdema is one of the symptoms of suppuration, and when the collection of matter is very deeply situated, sometimes leads to its discovery, as is exemplified in cases of empyema.

There is a species of œdema, accompanied with a degree of heat, pain, &c. in the part, and which, in short, seems combined with phlegmon. In this case, cold evaporating lotions, the application of leeches, and the exhibition of saline purgatives are proper. An erysipelatous œdema is also met with, in which the treatment should very much resemble what is explained in the article *Erysipelas*.

ŒSOPHAGOTOMY. (From *œsophagus*, and *τέμνω*, to cut.) The operation of cutting into the œsophagus, in order to take out of it any foreign body which lodges in it, and can neither be extracted through the mouth, nor pushed down into the stomach, though its removal is absolutely necessary for the preservation of the patient's life. A substance, above a certain size, lodged in the upper part of the œsophagus, not only obstructs deglutition, but by its pressure against the trachea, produces the most urgent symptoms of suffocation. In this circumstance, if relief cannot be expeditiously afforded in any other manner, and *the situation of the foreign body is denoted by a prominence distinguishable in the neck*, œsophagotomy should be practised without delay. However, when the symptoms are pressing, yet unattended with any possibility of feeling the foreign body, either externally or with a probang, desperate as the situation of the patient may be, modern surgeons do not sanction the practice. And this difference from the opinion of the first proposers of œsophagotomy, does not arise so much from any reflections upon the greater difficulty of the operation in this circumstance, as from the consideration of its being unlikely to answer the only purpose which makes its performance at any time proper, viz. that of enabling the practitioner to extract with reasonable certainty the substance, whose continuance and pressure in the œsophagus are the immediate cause of the patient's danger. Hence, when the symptoms of suffocation are extremely urgent, but the foreign body produces no external prominence in the neck, the surgeon should in the first instance perform tracheotomy, so as to obviate the imminent peril arising from the impeded state of respiration, and afterward try such measures for the removal of the substance lodged in the œsophagus, as experience points out as most likely to prove successful. Though œsophagotomy was cursorily mentioned by Verduc in his "Pathologie Chirurgicale," Guattani, formerly a distinguished surgeon at Rome, is entitled to the honour of having published the first valuable observations on the subject.—(*Mém. de l'Acad. de Chir. t.* 3, 4*to.*) Guattani proved by experiments that the operation might be safely performed upon dogs, which recovered after it very well, and he demonstrated on the dead body that it was equally practicable on the human subject. Nay, what is still more to the point, he brought forward two instances, in which the practice had been successfully adopted on living patients. "In May, 1738, Goursauld, a surgeon at Coussat-Bonneval, in Limousin, was called to a man, in whose œsophagus a bone was lodged, an inch long and half an inch broad. Various ineffectual endeavours were made to force it down into the stomach, and, *as it was perceptible on the left side of the neck*, Goursauld ventured to make an incision for its extraction. The bone was thus easily taken out, no bad symptoms followed, and the wound healed up favourably with the aid of a uniting bandage. For six days the patient was not allowed to swallow any kind of food, but was nourished entirely with clysters. According to Morand, a similar operation was performed with equal success by Roland, surgeon-major of the regiment of Mailly."—(*Mém. de l'Acad. de Chir. t.* 3.)

Although the deep situation of the œsophagus among the most important parts of the neck, makes œsophagotomy an operation of considerable delicacy in the hands even of a skilful surgeon, and one of great danger in those of a man deficient in anatomical knowledge, and ignorant of the right way of proceeding, yet the propriety of performing it, under the circumstances which have been specified, is universally admitted. When, however, I refer to the delicacy and difficulty of the operation, I am meaning a case in which a deliberate dissection is made down to the œsophagus without any guidance from the projection of the foreign body within it; a case in which my views of the subject lead me to think, contrarily to those of Guattani, that the experiment would generally be attended with no practical benefit; which is also the sentiment of Baron Boyer For with respect to open-

ing the œsophagus, with the view of tracing a substance in it not externally perceptible, and either of taking hold of the same substance with forceps, or pushing it down into the stomach with other instruments introduced through the incision, as suggested by Guattani, the chances of success must be too small to justify a practice in which it is above all things of consequence to have the guidance afforded by the prominence in the throat, as a test of the foreign body being actually lodged in the œsophagus, and capable of being removed from it by the proposed operation. Indeed, the uncertainty of being able to reach and extract the foreign body, when its precise situation is not indicated by any external swelling, appears to me an objection of greater validity than any consideration either of the increased difficulty of cutting into the œsophagus under these circumstances, or of the usual consequences of such an incision after it has been accomplished; because the practicable nature of the operation, and the tendency of wounds of the œsophagus to heal favourably, when not complicated with other mischief of too serious a description, are facts proved beyond the possibility of dispute. In attempts at suicide and murder, and in cases of gunshot injury, the œsophagus is sometimes wounded, together with other parts in the neck, and yet the patients frequently recover; and when they die their fate seems to depend rather upon other unfavourable circumstances in their cases, than upon the accidental injury of the gullet. The cures of wounds of the neck, involving the latter tube as well as the trachea, are reported by numerous writers, B. Bell, Desault, Bohnius, &c., and some have fallen under my own observation. If it were necessary to substantiate this point farther, I might cite the instance recorded on the authority of Dr. James Johnson, where a man recovered after the larynx had been completely severed between the thyroid and cricoid cartilages, and one-half of the caliber of the œsophagus divided.—(See *Hennen's Military Surgery*, *p.* 364, *ed.* 2.) But supposing a wound of the œsophagus, abstractedly considered, were more dangerous than it really is, the question of the propriety of œsophagotomy would not be materially affected by it; because the operation is never recommended, except as a matter of necessity, and without which the patient would have no chance of preservation.

As the œsophagus does not descend exactly in a straight line, between the trachea and vertebræ, but inclines rather to the left side of the spine, Guattani directs the left side of the neck to be preferred for the performance of œsophagotomy. But Boyer has justly remarked, that as the operation should never be attempted unless there be projection of the foreign body, the place for the incision is always to be determined by the situation of the projection, the left side being chosen only when the prominence is either most distinguishable there, or at all events not less than on the opposite side of the neck.—(*Traité des Mal. Chir. t.* 7, *p.* 192.)

The parts which cover the œsophagus from the middle and external part of the neck to the upper part of the sternum, are the skin, fat, cellular substance, muscles proceeding from the sternum to the larynx, the thyroid gland, the thyroid arteries and veins, the trachea, the recurrent nerve, &c. Guattani, who preferred the left side of the neck, recommended the following mode of operating. The patient is to sit on a chair, with his head inclined backwards, and steadily supported by an assistant. The skin having been pinched up into a transverse fold, an incision is to be made in the integuments from the upper part of the sternum. The cellular substance between the sterno-hyoideus and sterno-thyroideus muscles and trachea is next to be divided. With two blunt hooks the lips of the wound are to be kept open; and on separating the cellular substance at the side of the trachea with the aid of the finger and a few strokes of the knife, the œsophagus will be seen. The lower part of this tube is then to be opened, and the wound in it enlarged with a pair of curved blunt-pointed scissors, a director being employed if any difficulty arise. With a small pair of curved forceps, similar to those used for the extraction of polypi, the foreign body may then be removed. According to Guattani, the wound will serve for the extraction of the foreign body, whether this be situated above or below it, and he asserts that the opening will even be useful when the extraneous substance has passed so far down that it cannot be taken out, as it can now be easily pushed into the stomach. Guattani lays great stress on the usefulness of endeavouring to unite the wound, and adverts to his experiments, proving that, in animals, wounds of the œsophagus heal very favourably. If, says he, the vein which brings back the blood from the inferior parts of the thyroid gland, and runs into the subclavian, happen to be cut, the hemorrhage may be stopped with a dossil of lint held upon the aperture in the vein during the operation, and afterward, if the bleeding continue, compression or a ligature is to be employed. The recurrent nerve, if at all likely to be touched with the knife, is to be cautiously drawn a little out of the way with the blunt tenaculum. Guattani also particularly insists upon opening the œsophagus as near as possible to the trachea, especially at its upper part, where the artery which goes from the subclavian to the thyroid gland sometimes runs. When the foreign body requires an ample opening, and particularly when the thyroid gland is enlarged, Guattani approves of separating this part a little from the side of the trachea.—(See *Mém. de l'Acad. Chir. t.* 3, *4to.*)

There can be no doubt that Guattani's directions for finding the œsophagus are very good; but his chief defect is that of representing the place for the incision as being always the same, whereas it ought to be partly regulated by the situation of the foreign body itself. However, his advice to make the incisions close to the trachea appears to me more judicious than that recently delivered by Mr. Boyer, who directs them to be made through the cellular substance between the sterno-hyoideus and sterno-thyroideus muscles, and the omo-hyoideus (see *Traité des Mal. Chir. t.* 7, *p.* 193, 8*vo. Paris*, 1821); in which method he quits the trachea, which is the best guide to the œsophagus, and approaches unnecessarily the large blood-vessels of the neck. Yet I agree with Boyer respecting the general impropriety of attempting œsophagotomy when the situation of the foreign body is not indicated by any prominence in the neck, and the prudence of determining the place of the incision in a great measure by such projection. Boyer also cautions the operator to let his incisions always be made in such manner as to leave unhurt the trachea and recurrent nerve at the inner edge of the wound; the carotid and internal jugular vein at its outer edge; the superior thyroideal vessels above; and the inferior ones below. With this view, the cellular substance is to be slowly divided layer by layer, and the blood repeatedly absorbed with a sponge; but if any vessel bleed freely it is to be immediately tied.

After the operation, an elastic gum catheter should be passed from one of the nostrils down the pharynx and œsophagus, by which means the requisite food and medicines may be injected into the stomach without any risk of their passing through the incision and retarding the cure. But a still stronger motive for this practice is the avoidance of the convulsive action of the muscles in deglutition; a source of very hurtful disturbance to the parts. Before the advantages of this contrivance were duly appreciated, the patient, for the first week, was allowed to swallow scarcely any thing, and was kept alive with broths injected up the rectum.

In Graefe and Walter's Journ. (*b.* 5, *p.* 712), Vacca-Berlinghieri has described an instrument with which he conceives that this operation may be more easily and safely done than in any other manner. It is passed into the œsophagus as far as the lower angle of the external incision, and then by means of an olive-shaped knob, which is moved by a spring, it makes the parietes of the œsophagus protrude at the wound.

ŒSOPHAGUS, *Foreign Bodies in the.* There are few situations in which foreign bodies lodge more frequently than in the œsophagus; a fact explicable by the consideration of the function of this tube, the nearness of part of which to the windpipe at the same time accounts for the frequent danger of suffocation, when a substance above a certain size is lodged in it. The lodgement often takes place at the lower part of the pharynx or beginning of the œsophagus, and sometimes just above the diaphragm; but very rarely in the intervening portion of that canal.

Foreign bodies liable to lodge in the œsophagus are, not only articles of food, such as pieces of crust or ment imperfectly chewed, the yolk of an egg boiled very

hard, and not masticated, a chestnut, or small apple, &c.; but also various substances which are accidentally swallowed either alone or together with the food, such as pieces of bone, stones, pins, needles, buttons, pieces of money, knives, forks, scissors, spoons, keys, &c. These latter articles, by lodging in the pharynx or œsophagus, may occasion very bad and fatal symptoms, and if forced down into the stomach may produce effects of a not less serious description. Hence an immediate attempt should always be made to extract them. For this purpose the fingers may be employed, and, if they will not reach far enough, a pair of long curved forceps should be used. But no instrument seems better calculated for cases in which the body lodged in the œsophagus is not too wide, than the urethra-forceps invented by Mr. Weiss of the Strand, and used by Sir A. Cooper for the removal of calculi, under a certain size, from the bladder.—(See *Med. Chir. Trans. vol.* 11.) Nooses of wire, and bunches of thread with a multitude of nooses, fastened upon the end of a probang, and a piece of sponge fixed on the extremity of the same instrument, or on that of the strong wire stilet of a long elastic gum catheter, and various other contrivances have been made with the view of extracting different articles from the œsophagus. The bunch of thread seems well calculated for catching hold of small substances, like fish bones, needles, &c.; and the sponge, when expanded with moisture and withdrawn, will sometimes bring up articles, which, on its introduction, it had passed in its dry and diminished state. When the stomach is full, the excitement of vomiting has sometimes answered; but if the foreign body be sharp and pointed, the method is not free from danger, and, instead of relieving the patient, may put him to great pain, and bring on violent inflammation of the passage, and the most distressing symptoms. Some practitioners, however, are advocates for an emetic, and when the patient is totally incapable of swallowing, it has been proposed to inject a solution of tartarized antimony into the veins. —(See *Chelius, Handb. der Chirurgie, b.* 2, *p.* 105.)

When the substances are not of a very hurtful kind, and cannot be extracted, they must be pushed down into the stomach with a large bougie, or a whalebone probang, fifteen or sixteen inches long, and to the end of which a piece of fine sponge is securely fastened. But such practice is not advisable, when the foreign bodies have a sharp, pointed form, so as to be likely to prove a source of at least equal danger and suffering, if placed in contact with the inner surface of the stomach. Experience proves, that hard angular substances and pointed bodies, like nails, pins, needles, &c. which surgeons have not ventured, or not been able, to force down into the stomach, have often made their way after a time to the surface of the body, where an abscess has formed, out of which they have been discharged.

When hard, irritating bodies have either passed of themselves, or been pushed with a probang into the stomach, their ill effects should be counteracted, and their passage through the bowels promoted with mucilaginous draughts, containing the oleum amygdalarum, or oleum ricini. When the substances lodged in the œsophagus, can neither be extracted, nor pushed down into the stomach, if respiration be not dangerously obstructed, and liquids can yet be swallowed, the wisest plan is to avoid irritating the passage with the farther use of instruments, and leave the case to nature, that is to say, as far as manual interference is concerned; for bleeding and mucilaginous oily draughts may be in some cases useful. But when the lodgement of a foreign body in the œsophagus dangerously obstructs respiration, and the substance itself cannot be felt externally, the patient would perish, if some means of facilitating the breathing were not immediately adopted; and, under these circumstances, perhaps, the most prudent plan would be to make an opening in the trachea.—(See *Bronchotomy.*) The subsequent treatment, with reference to the foreign body itself, might be determined by the circumstances of the case.

In this part of surgery, one fact deserves to be particularly remembered, which is, that after a sharp, hard substance has been either ejected, or propelled into the stomach by nature or art, the same painful sensations in the throat frequently continue a certain time afterward, which were experienced while the foreign body was actually lodged in the passage. These sensations, however, are only owing to the manner in which the œsophagus has been irritated, and, consequently, would be seriously aggravated by the farther unnecessary introduction of probangs and other instruments.

There may be cases in which the patient would lose his life by suffocation, if a foreign body of considerable size were not taken out of the œsophagus, so as to remove the compression of the trachea. Here, if it could neither be extracted, nor pushed into the stomach by common means, and its situation were indicated by any hardness or prominence in the neck, an operation would be necessary for its removal.—(See *Œsophagotomy.*)

A foreign body, not large enough to cause danger of suffocation by pressure on the trachea, may yet bring on fatal symptoms, as is exemplified in a case which fell under the notice of Guattani. As a man was throwing up a boiled chestnut in the air, and catching it in his mouth, it passed down his throat, and he was immediately seized with a difficulty of swallowing, and sent to the hospital. However, as he breathed and spoke with facility, and had vomited since the accident, which happened when he was tipsy, the story of his having swallowed the chestnut was disbelieved. His symptoms grew worse, and he died on the 19th day. Guattani made an incision in the left side of the neck, below the larynx and thyroid gland, which was considerably swelled, and soon came to a large abscess formed around the portion of the œsophagus enclosing the chestnut.

When the extraneous body is sharp and pointed, so as to stick in the mucous membrane of the passage, and it cannot be removed, nature will sometimes expel it herself, without any dangerous symptoms being the consequence. The foreign body is gradually loosened by ulceration, and is then either ejected by vomiting, or descends into the stomach, whence it is voided either through the bowels with the feces, or, as is more common, by making its way through some part of the alimentary canal, and approaching the surface of the body where an abscess forms, out of which it is discharged. In other instances, foreign bodies, like pins and needles, which cannot be removed, pierce the œsophagus itself, gradually pass completely out of this canal, and afterward travel to remote parts of the body, without exciting much inconvenience, until, perhaps, at the end of some years, they come near the surface of the body in a very remote situation from the throat; and an abscess is produced, in which they are unexpectedly found. However, this transportation of sharp-pointed substances from one part of the body to another, which is effected by a process in which the absorbents have a principal share in the work, is not conducted in every instance with so little disturbance, and when foreign bodies of this description come into contact with particular organs, symptoms of a dangerous and fatal kind may be excited.

The great art of passing any instrument down the œsophagus for surgical purposes, consists in putting its extremity at once directly against the posterior part of the pharynx, and keeping it closely against the vertebræ, so as to avoid touching the epiglottis. The knowledge of this circumstance will be found extremely useful in passing probangs and bougies. When elastic gum-catheters are intended to be left in the passage, they are introduced down the pharynx from one of the nostrils, and, being secured, they serve for the conveyance of liquid food and medicines into the stomach with great advantage in many cases, either where the patient cannot swallow at all, or where the disturbance of swallowing would be attended with considerable harm. When, however, the plan is not to leave the instruments introduced, as Boyer observes, they may be passed through the mouth.

ŒSOPHAGUS, *Strictures, and other Diseases of the.* Properly speaking, a difficulty or impossibility of swallowing should not be regarded as a disease itself; but only as a symptom of different affections, to which the organs of deglutition are liable, or of other diseases in the vicinity of the pharynx and œsophagus. The object of the present article is not the consideration of all the diseases which may produce dysphagia, as a symptom, but chiefly to notice this effect, as depending upon spasm, paralysis, or some morbid change of structure affecting the pharynx or œsophagus.

Spasmodic dysphagia, as Baron Boyer has remarked,

principally occurs in nervous individuals, hysterical females, and hypochondriacal men. It is sometimes an attendant on fevers; it is declared to be constant in hydrophobia and epilepsy, and occasionally present in particular forms of mania.—(*Traité des Mal. Chir. t.* 7, *p.* 151.) However, with respect to hydrophobia, the foregoing assertion should be received with some qualification, for reasons so fully detailed in another part of this work (see *Hydrophobia*), that it is unnecessary here to dwell upon the subject. Spasmodic dysphagia is said also to be sometimes a consequence of taking cold drink after a violent fit of anger; of strong impressions on the imagination; of worms in the stomach, &c.

When the spasm is situated in the pharynx and upper part of the œsophagus, and is considerable, neither solids nor liquids can be swallowed, and the patient has great pain and a sense of constriction in his throat. When he tries to swallow any thing soft, or even fluid, he is seized with acute pain, insufferable nausea, and violent agitation of the whole frame. In this case, the spasm is never restricted to the pharynx and upper portion of the œsophagus, but extends to other organs, the inability of swallowing coming on in the midst of numerous other spasmodic symptoms exceedingly complicated, and sometimes of a very alarming nature. When it is the middle, or lower part of the œsophagus, which is concerned, as is frequently the case in hysterical women, the food passes through the pharynx and unaffected portion of the œsophagus with tolerable facility: but as soon as it reaches the seat of the spasm, it is either stopped or descends farther with great difficulty and effort. Liquids, especially when warm and swallowed slowly in small quantities at a time, usually pass down with more ease than solid substances. When the matter to be conveyed into the stomach reaches the point of obstruction, the generality of patients are attacked with pain extending along the spine between the shoulders, and sometimes shooting to the stomach, which is considerably disturbed, and often discharges its contents. In some cases, however, no no such pain is experienced, and whatever the patients try to convey into their stomachs regurgitates quietly into their mouths. Although spasmodic dysphagia is mostly complicated with other marks of disorder of the nervous system, it is sometimes unattended with any particular impairment of the health.—(*Boyer, t.* 7, *p.* 152.)

As the treatment of spasmodic affections of the pharynx and œsophagus belongs rather to the physician than the surgeon, I shall be very brief on the subject. The removal of the cause of the infirmity, that is to say, of the particular state of the mind or constitution giving rise to the spasm, is the principal thing at which the practitioner should first aim. Thus Boyer cured an hysterical woman of a difficulty and dread of swallowing solid food by attending her at her meals twice every day for a month, and gradually convincing her of the absurdity of her apprehension of being suffocated by attempting to swallow solid aliment.—(*Vol. cit. p.* 154.) Sauvages makes mention of an hysterical female, whose difficulty of swallowing was cured by a regimen consisting of regular exercise, cold bathing, and milk-diet. The most successful remedies, however, are said to have been camphor in large doses, and opium taken in draughts or pills, or administered in clysters: blisters and cupping-glasses applied to the nape of the neck, or to the epigastrium. Anodyne embrocations are also stated to have been useful. At the present day, the common idea, that many anomalous affections depend upon disorder of the liver and digestive organs, leads to the frequent employment of the compound calomel pill, and decoct. sarsaparillæ, with draughts of senna, rhubarb, and gentian *pro ré natâ*.

Dysphagia may originate from a weakened or paralytic state of the muscular fibres, which enter into the structure of the pharynx and œsophagus. The affection may be either symptomatic or idiopathic. The first case frequently occurs in febrile diseases, and is generally set down by writers as a very unfavourable omen. The idiopathic form of the complaint may be complete or incomplete, and is chiefly seen in persons of advanced age, though occasionally the patients are young and in the prime of life. The causes may be said to be little or not at all understood, and the only remark which can be safely made respecting them is that they are usually connected with constitutional derangement.

With regard to the symptoms of paralysis of the œsophagus, when the disorder is complete, deglutition is absolutely prevented, and, if the patient tries to swallow, the food lodges in the pharynx, and sometimes produces violent fits of coughing. Some patients eat solid substances with moderate facility; but find more or less difficulty in taking liquids. Others can swallow hastily a large quantity of fluid at a time, yet cannot drink slowly and a little at once. Morgagni relates an instance of still greater singularity, which was an ability to swallow all kinds of food very well, except the last mouthful, which always remained in the œsophagus until the next repast.—(*De Sed. et Caus. Morb. epist.* 28, *art.* 14.) In cases of dysphagia from paralysis the patient suffers no pain, nor sense of choking; if the neck be examined, no hardness nor swelling can be felt; and a probang descends down the gullet without the slightest impediment.—(*Boyer, t.* 7, *p.* 158.)

In its duration and termination dysphagia from paralysis presents considerable variety; the complete paralysis sometimes proves rapidly fatal, not however, as I conceive, on account of the affection of the œsophagus alone, but other complications, and the exhaustion arising from inadequate nutrition. Thus, Tulpius relates an instance, in which a woman died on the seventh day from the commencement of the inability to swallow, notwithstanding every endeavour was made to support her with nourishment thrown up the rectum, which was the only thing that could be done, as she would not allow a tube to be passed down the œsophagus. In other cases, the patients live a considerable time, and afterward perfectly recover, and this sometimes under the disadvantage of having been entirely supported for several weeks with broth-clysters, as we find exemplified in a case recorded by Ramazzini. Certain examples are also reported, in which the patients had their food forced into the stomach by means of probangs for years, and either ultimately recovered their power of swallowing, or in this manner prolonged their days without any cure taking place.—(*Stalpart van der Weil, vol.* 2, *Obs.* 28; *Willis, Pharm. Rat. sect.* 2, *cap.* 1, *p.* 45.)

Paralysis of the œsophagus is to be treated on the same principles as other paralytic affections; a subject which I shall not be expected to discuss; but it is of importance that practitioners recollect, in these cases, the very essential service derived from the use of elastic gum catheters, with which the requisite food and medicines may be injected into the stomach.

Dysphagia, from organic disease or morbid change of structure, is the most frequent case, and generally the most difficult of cure. In dissections, the parietes of the œsophagus are often found considerably thickened, indurated, and scirrhous, or sometimes almost cartilaginous, and even ossified. The parts where the pharynx terminates in the œsophagus and where the latter tube joins the stomach, are occasionally converted into thick scirrhous rings, with or without ulceration, exactly in the same manner as the pylorus. In one fatal case of dysphagia from disease of the cardiac orifice of the stomach, the œsophagus was found distended into a sac, reaching from two inches below the pharynx down to the diseased part, and capable of holding two quarts.—(*T. Purton, in Med. Phys. Journ. Dec.*, 1821.) But such diseases are not restricted to the above-mentioned parts of the œsophagus, but sometimes occupy other points of the passage. Neither is the organic disease producing a difficulty or impossibility of deglutition always situated in the coats of the œsophagus itself: for the surrounding parts are subject to various diseases which may have the same effect. Thus, dysphagia may depend upon enlargement of the thyroid gland; tumours formed between the trachea and œsophagus, or at some other point near the latter tube; swelling and induration of the thymus gland; aneurism of the aorta; enormous enlargement of the liver; and diseased lymphatic glands in the vicinity of that portion of the œsophagus which is covered by the peritoneum, and the largest of which glands are situated near the fifth dorsal vertebra, just at the point where the œsophagus inclines a little to the right side to make way for the aorta.—(*Boyer, t.* 7, *p.* 162.)

This last author sets down every case of dysphagia depending upon organic disease of the œsophagus as incurable; and with respect to the cure of other ex-

amples, in which that tube is compressed by swellings in its vicinity, as these are almost always beyond the power of medicine and surgery, the prognosis is nearly as unfavourable as where there is a change of structure in the œsophagus itself. There are no unequivocal symptoms by which a case of dysphagia from enlargement of glands in the vicinity of the œsophagus can be known from several other forms of the complaint. Hence, it is difficult to estimate the correctness of certain cases recorded by Ruysch (*Advers. Anat. Med. Chir. dec.* 1, *art.* 10, *p.* 24), and Haller (*Opuscul. Pathol. obs.* 71), where dysphagia, stated to have been produced by enlarged lymphatic glands, was cured by mercurial frictions, or pills composed of calomel, aloes, and camphor. As Boyer justly remarks, these accounts of the nature of the diseases thus cured are the more doubtful, inasmuch as the resolution of chronic swellings of lymphatic glands, even when externally situated, is very difficult and frequently impracticable, notwithstanding the use of topical applications may here be combined with the exhibition of internal medicines.—(*T.* 7, *p.* 169.) However, dismissing the question, whether the cases really arose from the pressure of enlarged lymphatic glands or not, the facts of the cures having taken place under the use of mercurial medicines, are of themselves interesting. Several writers consider that there is a great analogy between certain forms of constriction of the œsophagus, and strictures of the urethra, and Mauchart recommended the two diseases to be treated on the same principles with bougies and elastic gum catheters. Baron Boyer, however, represents this doctrine as completely erroneous, declaring that the affection of the œsophagus is of the nature of scirrhus, and absolutely incurable. He relates one case in which a woman's life was prolonged by the use of an elastic gum catheter, though it proved of no service as a means of permanently dilating the diseased part; and, notwithstanding nourishing liquids were plentifully injected into the stomach, the patient suffered a good deal from hunger, and died exhausted about three years after the beginning of the disorder. This case, however, cannot be received as a proof of the inefficacy of bougies for what is commonly implied by a stricture of the œsophagus, because the nature of the disease was not ascertained by an inspection of the œsophagus after death, and the case might have depended upon some organic disease either of this tube or the parts in its vicinity not classed by the generality of modern writers with strictures of the passage.

The following are some of Sir Everard Home's sentiments respecting these last cases.

As the œsophagus is required to be wider at one time and narrower at another, in order to be fitted for conveying the different kinds of food into the stomach, it is nearly under the same circumstances with respect to the formation of stricture as the urethra. For obvious reasons, strictures of the œsophagus are much less frequent than those of the urethra. However, they are by no means uncommon, and produce symptoms even much more distressing and dangerous than those which ordinarily arise from analogous obstructions in the passage for the urine.

Of course, the most remarkable symptom of a stricture in the œsophagus is the difficulty of swallowing, which must be greater or less according as the obstruction is more or less complete. Sometimes no solid food whatever can pass down into the stomach, and fluids can only descend with great difficulty and in very small quantities. This is, in some instances, attended with considerable pain, which extends along the fauces to the basis of the skull, and through the Eustachian tube to the ear. The pain sometimes returns at intervals and lasts a considerable time, even when no effort is made to swallow. If a bougie of proper size be introduced down the pharynx, it will often be stopped by the stricture just behind the thyroid or cricoid cartilage; for, from Sir Everard Home's remarks, it appears that the obstruction is generally as high up as this situation. However, there are other cases in which the obstruction is only of a spasmodic nature, and in these a bougie may be passed quite down. It is curious, that strictures high up in the œsophagus often occasion ulceration in this tube very low down towards the stomach, just as strictures in the urethra occasion ulceration in that passage towards the bladder. This is most apt to occur when strictures of the œsophagus have been of long continuance, and may arise from the efforts in retching, which frequently come on, and must strain the parts already deprived of their natural actions, and of the benefit of the secretions with which they are lubricated in a healthy state. When such ulceration takes place, the characters of the original disease are lost; and when the ulceration extends upwards, the stricture itself may be destroyed. A bougie introduced under such circumstances will, in general, have its point entangled in the ulcer; and when so skilfully directed as to go down into the œsophagus, it will meet with a difficulty while it is passing the commencement of the ulcerated part of the œsophagus, and another impediment where it leaves the ulcer, and enters the sound portion of the œsophagus below. These two resistances may lead to the supposition, that there are two strictures while, in fact there is not one, only ulceration as above described.

Strictures in the œsophagus are sometimes so complete, that swallowing even fluids is utterly prevented; the patient is obliged to have all nourishment injected *intra anum*, and in general soon perishes in a most emaciated condition.

Though any part of the œsophagus is liable to the kind of contractions forming strictures, the part immediately behind the cricoid cartilage, where the pharynx ends and the œsophagus begins, is the most frequent seat of the obstruction. Those which are situated farther down do not so easily admit of being examined and relieved by any surgical operation. Strictures of the œsophagus occupy but a small extent of the passage, consist of a transverse fold of the internal membrane, and are attended with little thickening of the adjacent parts. These latter circumstances are such as render the disease capable of receiving relief either from simple or armed bougies.

There are two other diseases of the œsophagus which have symptoms similar to those of strictures. One is a thickening of the coats of the œsophagus, which extends to the surrounding parts, and generally ends in a cancer or an incurable disease. The other affection is an ulcer of the lining of the passage, commonly situated a little below the seat of the stricture on the back part of the tube. In the early state, these diseases can only be distinguished from a stricture by an examination with a bougie; afterward their nature becomes clear enough from other symptoms which arise. Strictures also take place more commonly in young subjects; the other two diseases in the more advanced periods of life.

Sir E. Home has found, that a bougie can be more easily introduced into the œsophagus when the tongue is brought forwards out of the mouth. This gentleman remarks, that when a bougie is passed, with a view of learning the nature of the case, if it passes down to the distance of eight inches, measuring from the cutting edge of the front teeth in the upper jaw, its extremity has gone beyond the usual seat of stricture. If it be withdrawn without any resistance, the aperture in the œsophagus must then be larger than the bougie employed. But if the bougie stops at the distance of six inches and a half, or even lower, it must be retained there with a uniform pressure for half a minute, so as to receive on its point an impression of the surface by which it was opposed. If the end of the bougie retains its natural form, or nearly so, and there is an indentation on one side of it, or all around it, the surgeon may conclude there is a stricture. On the other hand, should the bougie descend without impediment as far as seven inches and a half, and when withdrawn the surface of its point appear irregular and jagged, the disease is an ulcer on the posterior part of the œsophagus.

The mode of treatment adopted by Sir E. Home consists either in passing a common bougie occasionally through the stricture, and employing one of a larger size, in proportion as the dilatation of the obstruction is effected; or else in introducing an armed bougie at convenient intervals. The views which I take of the disease would lead me to prefer giving a full and fair trial to the employment of elastic gum catheters. [The following judicious and practical observations on the treatment of stricture of the œsophagus are communicated to me by Professor Jameson of Baltimore, to whose ingenuity I have already borne testimony in other parts of this work, and to whom our profession is largely indebted for many original and important improvements. As so little is said on this subject by surgical authors, and so much less known by practitioners, I have been unwilling to deteriorate from the utility of his communication, and have therefore inserted it entire. But as this Dictionary necessarily excludes cuts and engravings of every kind, I am under the necessity of referring for the size and configuration of his ball-probes, bougies, and probangs to the *Medical Recorder for* 1825.

STRICTURE OF THE ŒSOPHAGUS.

"There are perhaps few subjects connected with surgery upon which we have less information of a practical nature than stricture of the œsophagus, and yet we know by the reports of post-obituary appearances that such diseases are sometimes met with; and we cannot well imagine a more distressing form of disease than the gradual obliteration of the œsophageal tube. We find some notice of its treatment in the works of Boyer and other French authorities; also in the works of Mr. Home and Mr. C. Bell. These authorities recommend bougies, tubes, caustic, &c. Our observation has led us to believe that none of these means are well suited to the removal of œsophageal stricture. And for ourselves, we should shudder at the idea of applying caustic to a tube so much out of reach, and so very important to our existence.

We shall not detain the reader, however, with any detail of the various methods practised and recommended by authors; but shall briefly state our own method, which we think better suited to the malady in view than any other which we have heard of or tested.

In order to point out the advantages of our method of treating stricture of the throat, it will be necessary to state some of the particulars of a very interesting case. The subject of this case was a lady of refined mind and feeble and delicate habit of body, aged upwards of forty years. She has experienced much difficulty in swallowing solids for two years, but can swallow liquids with tolerable facility. Her food must be chewed with much care, and even then it is only pulpy articles that can be managed with any sort of comfort: animal food can only be taken at times, and with great difficulty. There is no pain or soreness in the part, nor is there any interruption in her breathing; but at times, after eating, she feels an unpleasant stinging sensation just below the lobe of the left ear. She has been dyspeptic, and the affection of the throat ascribed by several respectable physicians to that disease, to imagination, &c.

The patient is not aware of the cause of the disease, but dates its commencement from an accidental choking in swallowing a piece of beef. From that time there has been more or less disability in swallowing, and she has been subject to occasional choking at table. The disease formed suddenly to considerable extent; but has been gradually increasing, and at this time she is seriously threatened with starvation. In examining the throat we perceived a sort of crepitus from wind; and we were informed, that the patient was greatly annoyed by a strange noise which proceeded from about the part upon which we pressed. We were convinced from this circumstance, that the œsophagus was somewhat dilated below the stricture, and afforded a lodgement for air which might occasionally rise up from the stomach.

We ascertained, by feeling, that there was no tumour at this point in the tube, or which might press upon it. We now attempted to pass down a probang, but found it arrested about the cricoid cartilage; a common flexible bougie was next tried but could not be passed through the stricture. This examination was made on the 2d December, 1823. The next day, trials were again ineffectually made with the bougies.

We shall not stop to detail the daily remarks upon this case; let it suffice to say, that after trying various expedients, we devised the probangs, which may be seen in the *Medical Recorder for* 1825. On the 6th of December, we succeeded in passing the ball-probe marked No. 2; but not till after long trials with it and No. 1. The ball passed the stricture with a jerk, and we now satisfied ourselves that the stricture was confined to a small extent; and hence we perceive one of the advantages of using the ball-probe, as we could thereby measure the sides of the tube far better than with a flexible tube or bougie. We also ascertained that there was no very remarkable induration, although the parts were obviously much closed by swelling. It was several days before either of the ball-probes could be passed again.

By the 22d of the month, the parts having lost something of their sensibility, and the patient, supported by her good sense, had acquired the power of bearing the presence of the probang much better than at first. Having by this succeeded pretty well in the practice of introducing the ball-probes, but finding no improvement, it occurred to us, that as we could get the ball-probe through the stricture, we might pass a suitable probang on the same wire, and thus apply a little pressure, presuming on the certainty, that the wire would guide the probang through the contracted part. For this purpose we contrived the probang No. 1.

We operated by passing the ball-probe about two inches through the stricture, then its outer end was slipped through the hole in the probang, and having passed it (the probang) as far as the root of the tongue, the wire of the ball-probe and the staff of the probang were brought together, and the whole passed through the stricture. This was repeated for some time every second day, afterward every day, and at each time the probang was made to pass three or four times through the stricture.

After using the probang about three or four weeks, we could pass the ball-probe with facility; whereas, at first, the use of the ball-probe was attended with much difficulty and occasional disappointment. The probang passing freely through the stricture, and the power of deglutition having considerably improved, we commenced the use of the probang No. 2.

A few weeks were employed in the use of this second instrument. It was passed through the stricture with tolerable ease, but it was somewhat difficult to withdraw it. Some strain was put on the parts in drawing out the instrument, and in some degree interfered with her swallowing for some little time afterward. On one or two occasions, a little blood appeared in the mucus which was spit up, but it was mere streaks. The soreness was not considerable at any time, and although we were extremely anxious to avoid producing any soreness, we persisted in the use of the probang. We were soon led to believe, that an instrument so perfectly smooth, if cautiously managed, would tend to smoothen and heal the parts. We were aware of the advantages attending the use of well-polished sounds in stricture of the urethra.

No. 2 having been brought to pass through the stricture with great ease, after some weeks' employment of it, we commenced the use of No. 3. This instrument also passed with facility, and produced no soreness, but could only be passed through the obstruction by the aid of the ball-probe or guide. We now began from time to time to try the probang without the guide, but could never succeed.

As with No. 2 so with No. 3, we continued its employment some weeks, and then began with No. 4. This passed with tolerable facility, but if passed a little too low it occasioned very painful and indescribable feelings in the thorax; this we attributed to the distention of the nerves surrounding the œsophagus.

We have remarked in our notes of this case, that some weeks after using the probang No. 4, that the patient swallowed much better; but the stricture still closes after withdrawing the probang, so as to render it still somewhat difficult at times to introduce either of the ball-probes; the difficulty is, however, slight in comparison to what it was some weeks ago. No. 5 was now passed; its introduction was very painful for a few times, in consequence of which we left longer

intervals between the times of using the instrument, but never more than two or three days From this time nothing remarkable occurred in the case; the patient is quite comfortable in regard to swallowing, but, owing to our not being able to pass the probang without the guide, she was desirous of continuing the dilatation. And, indeed, we were fully impressed with the necessity of continuing to dilate for a length of time. The use of the instruments was continued once a day, Sundays excepted, till about the middle of September, at which time we were confined by fever, and there was a suspension of two months.

Upon our recovery, we resumed the use of the probang, and being desirous of ascertaining whether any material alteration had taken place, we passed the instrument lower than usual, perhaps a little lower than the sternum: she instantly started forwards, as if much alarmed, and stated that she had felt a most violent shock through the spine.

The case was about a year under treatment, deducting two months of lost time. The probangs would still not pass without the guide, but they could be passed through the stricture together with great facility. The patient could at this time partake with comfort of all sorts of diet, and swallow it with readiness. In short, there was a complete removal of the stricture, but there was some peculiar derangement at the termination of the pharynx, by which some part was made to act as a valve; but when the muscles of deglutition acted, this was removed or lifted, and the food descended; there was not now any traces of induration or thickening.

It seems proper to mention, that we could never succeed in making the probang pass into the pharynx by sliding it along the wire of the guide; but when it had reached the root of the tongue, the *wire* of the guide, already through the stricture, and the staff of the probang were held together, and thus introduced. By this procedure, the ball of the probe passed considerably lower than the probang, and probably went into the stomach; the wire, however, was too limber, and, armed as it was with its ball, it could not do any mischief. The wire is steel, and quite flexible, and much more free from sudden bends, which so readily take place in common iron wire.

We have deemed it necessary to give the foregoing case somewhat in detail, as well on account of its interesting peculiarities, as with a view of showing, that while the instrument which we used is probably the only thing which could have succeeded in this case, it has also the advantage of being well suited to all cases where dilatation is likely to succeed.

We tried various kinds of tubes in this case, but could not make them pass the stricture, though accustomed to pass the tube into the œsophagus. The stricture being mostly at the beginning of the œsophagus (that is, under the cricoid cartilage), the curvature of the stilet by which the tube must be passed, if made to suit the curvature of the pharynx and fauces, will strike against the anterior part of the lower part of the pharynx, and will not, therefore, be likely to pass downwards through the gullet. If we draw out the stilet, after fairly entering the tube into the pharynx, it will be too flexible to pass through any considerable stricture.

A material advantage possessed by the probang over the tube, is that of giving less interruption to the respiration. The tube, by pressing on the root of the tongue and epiglottis, will greatly obstruct the trachea, but the probang, having but a small shaft or handle, will only press moderately on the posterior side of the trachea at one point; and being guided through the stricture by the guiding wire, we can pass the probang with rapidity through the stricture.

The above case will serve to show with how much caution we proceeded, lest we might produce a sore in the strictured part. We did not venture to enlarge till several weeks use of each less size: this will appear obvious, by the fact of our continuing the treatment twelve months; and by the gradual manner in which we enlarged our probangs. Indeed, we hold it to be important, that the whalebone used for the handles of the probang should be slender, that they may not be forced in too hard.

We are persuaded that this method of treating stricture of the œsophagus will, in most cases at least, do away the necessity for the practice recommended of wearing a flexible tube in the part. At all events, in the case under notice, the tube could not have been made available, since nothing of the kind, nor even a probang, could be passed without the guide.

We have met with two very formidable cases of stricture since we treated the one above noticed. Before proceeding to notice them, it may be proper to state, that we saw our patient about a year since, when she was suffering very little inconvenience from her disease; and we readily passed our largest probang through the stricture. She is still alive, and we have no doubt still comfortable, as no report has been made to us.

The second case we saw was a woman engaged in a cotton factory in this city; she was suffering greatly from inanition, and the throat so contracted that our smallest probang was made to pass with some difficulty. After a few repetitions, the probang somewhat larger could be passed with facility; exact size not recollected.

Our attention was called to this case by our excellent friend the late Dr. Charles Smith of this city, who took charge of the case. In this case the probang seemed to answer extremely well; but Dr. Smith dying some months afterward, we lost sight of the patient and know not the termination of the case. Here, it may be observed, there was no necessity for the guide or ball-probe.

Our attention was called to a case of deplorable stricture of the œsophagus in the spring of 1829. Patient, a man about thirty years of age, of delicate make, and now much emaciated and debilitated from inanition. There was not much pain, but some soreness in the part; and when the probang was withdrawn, for several weeks it had a very fetid smell.

The patient was now reduced to very small quantities of milk, the only article containing nourishment that he could swallow; and often for many hours he could not swallow a drop of it or any thing else.

We commenced the treatment with our smallest ball-probe; it entered with considerable difficulty, and, indeed, required a degree of force which we did not much like to apply; but there was no alternative. A few repetitions rendered its passage more easy; and the patient, already aware of some relief, became reconciled to the instrument, and sat more quietly. The probang No. 1 was used after some time. Continuing our operations every second day, we very gradually enlarged till we could pass through the probang No. 4 with facility. In a few weeks, amendment was evident; the fetor of the throat disappeared; the patient began to take a little thick paste, made by beating gingerbread in milk; the consistence was gradually increased; afterward he could take bread, soaked soft in milk, or other fluids. His health and strength improved rapidly; and two months since he discontinued his calls, and removed to a factory a few miles from town.

In a word, then, we are persuaded, that by a patient and careful employment of the probang of smooth ivory, we shall frequently succeed in curing stricture of the œsophagus, even after the disease is far advanced. In the incipient stage of this disease, provided there be nothing specific in the diseased action, we will be sure to succeed.

We have been induced to believe that this tube (the œsophagus) is very little disposed to diseased action, except paralysis, and contraction with some induration from wounding or overstraining in swallowing hard or harsh articles of food.

Any explanation of the drawings seems to be unnecessary, as the application of them has been explained already; and a simple inspection of the plates is sufficient to convey a clear conception of the mechanism of the probang and the compound probang, with its guide or ball-probe. The handles are about fourteen inches long, a little more or less is not material, but of course it is essential that the ivory be turned by a good workman and thoroughly polished.

N.B. Be careful that the handle of whalebone is fastened to the ivory in such a way as to obviate all risk of its coming out as you withdraw the probang; inattention to this circumstance might lead to disastrous consequences, as the patient might suffocate before you could remove the ball of ivory, should it happen to get loose and be left in the throat. Mine are secured by a screw on the whalebone, fitting into a female screw in the ivory, and, after screwing as

tightly as possible, a rivet is passed through, so as to make all doubly sure.

We need hardly remark, that the tube is indispensably necessary in cases of paralysis of the œsophagus."—*Reese.*]

OLEUM CAMPHORATUM. ℞. Olei olivæ, ℔j. Camphoræ ʒ iv. Misce ut solvatur camphora. Sometimes employed for promoting the suppuration of indolent, particularly scrofulous swellings, which are to be rubbed with it once, twice, or thrice a day according to circumstances.

OLEUM LINI. In surgery, linseed oil is sometimes used as an application to burns, either alone or mixed with an equal quantity of the liquor calcis. It has also been applied to cancerous ulcers.

OLEUM ORIGANI. The oil of marjoram is often used for dispersing ganglions: the tumours are to be rubbed with it two or three times a day.

OLEUM PALMÆ CAMPHORATUM. ℞. Camphoræ ʒ ij. Olei palmæ ℔j. The camphor is to be reduced to powder, and the palm oil being melted, and suffered to become almost cold, is to be mixed with it. A mild topical stimulant, sometimes used for promoting indolent suppurations, especially those of a scrofulous nature under the jaw.

OLEUM RICINI. In surgical cases requiring the bowels to be opened with the slightest degree of irritation possible, the oleum ricini is the best and safest medicine. The usual dose is one large table-spoonful, which must be repeated every two or three hours, till the desired effect is produced.

OLEUM TEREBINTHINÆ. Oil of turpentine is employed externally as a stimulating liniment, and a styptic. In the article *Liniment* may be seen some formulæ, in which turpentine is the most active ingredient. It is sometimes exhibited internally for the cure of gleets.

OLEUM TEREBINTHINATUM. ℞. Olei amygdalæ ʒ ss. Olei terebinthinæ gutt. xl. Misce. In deafness occasioned by defective or diseased action of the glandulæ ceruminæ, Mr. Maule directs a little of this oil to be dropped into the patient's ear, or applied at the end of a small dossil of cotton. When a thin secretion takes place, the cure is also promoted by a small blister, which is placed as near the ear as convenient, and kept open with the savine cerate. The meatus auditorius externus must also be cleansed every day with a bit of soft cotton, affixed to a probe.—(See *Pharmacop. Chirurgica.*)

OMPHALOCELE. (From ὀμφαλὸς, the navel, and κήλη, a rupture.) A rupture or hernia at the navel.—(See *Hernia.*)

ONYCHIA. (From ὄνυξ, the nail.) An abscess near the nail of the finger.—(See *Whitlow.*)

ONYX. (From ὄνυξ, the nail.) A small collection of matter, situated in the anterior chamber of the aqueous humour, and so named from its being shaped like a nail. It is of the same nature as *Hypopium.* Maître Jean, Mauchart, and others, imply by the term *onyx*, a small abscess between the layers of the cornea.

OPHTHALMY. (From ὀφθαλμὸς, the eye.) *Ophthalmia. Ophthalmitis.* Inflammation of the eye. This is not only a consequence of several affections of the eye and adjacent parts, on the existence of which its continuance entirely depends; it is frequently the primary complaint, and too often the forerunner of such irreparable mischief as for ever bereaves the patient of vision.

Since every disease of the eye presents some differences, depending upon the nature of the disorder itself, and others, arising from the peculiar organization of the texture which happens to be principally affected, the characteristic appearances of ophthalmy must be subject to a vast number of modifications, according to the particular structure which is inflamed; and hence, sometimes one symptom of inflammation, sometimes another, chiefly predominates, while others are less conspicuous, and often scarcely distinguishable. Yet, says Beer, none of the characteristic marks of inflammation are ever entirely absent. This author represents the degree of pain as being proportioned in a great measure to the tough unyielding nature of the parts immediately around the inflamed texture of the eye, to the firm nature of the inflamed texture itself, and to the quantity of nerves with which such texture and the parts in its immediate vicinity are supplied. In proof of the truth of this doctrine, he instances whitlows and internal ophthalmy, where the pain is very severe; while inflammations of the conjunctiva, not extending to the deeper textures of the eye, are described as cases in which the pain is slight, because the structure affected is loose and yielding. But without scrutinizing every reason assigned by Beer for the varieties observable in the symptoms according to the texture which happens to be most affected, I shall briefly state a few other examples quoted by the same author. That the degree of redness as well as of pain varies considerably in different states of ophthalmy, is a fact universally known. In the beginning of the complaint, such redness is generally less perceptible than when the inflammation has attained its highest pitch; but it is not equally great in every individual nor in every species of ophthalmy, being sometimes more intense and diffused, sometimes less both in degree and extent. This diversity is referred by Beer, and probably with reason, to the texture affected in the eye being furnished with many considerable blood-vessels, obvious to the sight, or only containing vessels more concealed and rather filled with a colourless fluid than with red blood. The looseness or unyielding nature of the texture, is also represented as making a difference in the degree of redness. In inflammation principally affecting the conjunctiva and sclerotica, says Beer, the redness is so intense as to give the eye a frightful appearance, as is seen in chemosis; while in inflammation of the innermost textures of the organ, the redness is scarcely perceptible, and in the erysipelatous inflammation of the eyelids, the redness is very faint.—(*Lehre von den Augenkrankheiten, b. 1, p.* 34-36.)

Dr. Vetch remarks, that the conjunctiva is capable of being stretched to a great extent, owing to the loose structure of the cellular membrane on which it lies, and consequently little resistance is made to the enlargement of its vessels. From slight irritation they soon become distended with red blood, "but their tone or power of reaction is speedily exhausted, and if the exciting cause is not kept up in an increasing ratio, they quickly fall into a chronic or varicose enlargement, or again contract to the diameter of the serous vessels." On the other hand (as the same experienced writer has pointed out), inflammation of the sclerotic coat is slow in its commencement, and often insidious in its progress, even when its ultimate violence is great. *In the early stage of conjunctival ophthalmia, the inflammation is most observable at a distance from the cornea*, around which the membrane often preserves for a length of time its natural appearance. Precisely *the reverse takes place in the case of sclerotic inflammation, which invariably appears at the circumference of the cornea, forming a zone more or less complete about it, and most conspicuous above it;* the form and colour of the vessels being at the same time wholly different from those which appear in the course of conjunctival inflammation. *Intolerance of light* (says Dr. Vetch) *invariably accompanies sclerotic inflammation*, and is entirely unconnected with that of the conjunctiva.—(*On the Diseases of the Eye, p.* 10.) If the latter observation be strictly correct, it is to be inferred that in all common cases of acute ophthalmy, involving the conjunctiva on the front of the eyeball, the sclerotica is more or less affected, as in the beginning of the disorder, light may be said to be seriously annoying to every patient.

According to Mr. Travers, when the sclerotica partakes of the inflammation of the conjunctiva, the vessels which pursue a straight course to the margin of the cornea, are strongly distinguished, and have a somewhat darker hue than the areolar vessels upon the loose portion of the conjunctiva.—(*Synopsis of the Diseases of the Eye, p.* 128.)

Diversified as the pain, redness, swelling, and heat, the four characteristic symptoms of inflammation, may be in cases of ophthalmy, the incidental appearances in the eye are not less subject to numerous modifications. Thus, sometimes an extraordinary involuntary action of the muscles of the eyeball and eyelids, or of the secreting and excreting lachrymal organs, and of the Meibomian glands, may be noticed; and sometimes the action of all these parts is either diminished or completely stopped. These differences Beer refers to the latter parts being either themselves inflamed, or sympathizing with the inflamed texture of the eye. In the first case, the action of the muscles

and the functions of the lachrymal organs and Meibomian glands, are more and more interrupted in proportion as the inflammation increases, and must thus remain, while the inflammation lasts in its genuine form; but in the second case, they go on, and this even with greater activity, while the inflammation continues, and until it has ceased to become more violent.—(*B.* 1, *p.* 39.)

Acute ophthalmy, in general, when at all severe, and particularly when the inner textures of the eye are affected, produces a febrile disturbance of the whole constitution. This change from a local to a general indisposition takes place with greater certainty and quickness, in proportion as the inflammation is extensive the constitution irritable, the disorder of the eye neglected, and the mischief considerable, which is actually produced in the organ, whether accidentally or in consequence of unskilful treatment.—(*Beer, vol. cit. p.* 42.)

Many of the appearances and effects of ophthalmy are different, as the inflammation happens to be of an acute or chronic nature. And, as Scarpa has taken particular pains to impress upon the minds of surgical practitioners, every acute ophthalmy, though treated in the best possible manner, is never so completely resolved as not to be followed by a certain period, at which all active disturbance ceases, in the place of which a degree of chronic ophthalmy remains in the conjunctiva or lining of the eyelids; the effect either of local weakness in the vessels or of the continuance of a morbid irritability in the eye. As it occasions a diseased secretion in the organ, and a slow accumulation of blood and coagulating lymph, the inexperienced are apt to suppose that the acute stage is not yet entirely subdued, while it is completely so. Now, if the inculcations of Richter and Scarpa be correct, immediately the critical moment arrives when the acute stage changes into the chronic, attended with local weakness, it is of the highest importance to alter the treatment without delay, and to substitute for emollient relaxing applications, such as partake of an astringent corroborant quality, as the former only protract the turgescence of the vessels and the redness of the conjunctiva. "Quo major autem fuit inflammationis vehementia (says Richter), eo major plerumque sequitur partium affectarum atonia, eoque major opus est adstringentium et roborantium longo usu, ut auferantur penitus reliquiæ morbi," &c.—(*Fascicul. Obs. Chir.* 1, *p.* 109.)

It is on the accession of the second stage of ophthalmy that one may remark the sudden increase of redness in the inflamed texture, with a brown and afterward a blue tinge; actual extravasations of blood in the chambers of the aqueous humour; ecchymosis of the conjunctiva; a considerable increase of swelling; the decline and irregularity of the pain; the decrease of the inflammatory heat and throbbing; a sensation of cold and heaviness in the organ; and more or less œdematous swelling of the surrounding parts. It is also in the second stage that suppuration is liable to happen.—(*Beer, Lehre, &c. b.* 1, *p.* 46.) And in another page the same author observes, that the characteristic signs of the second stage of ophthalmy consist in the following appearances: while the redness and swelling undergo a sudden and striking increase, the hardness manifestly diminishes, and the pain becomes very unequal, and not continual; the secretions and excretions also, which, during the first stage, were completely stopped, commence again, but more copiously, and are of a very different quality from what they were in the state of health. The disorder is now quite in its second stage, and this is the time when purulent matter may begin to be formed.—(*B.* 1, *p.* 50.) According to Beer, the duration of idiopathic ophthalmy depends upon the circumstances of each individual case; first, the nature of the causes giving rise to the affection; secondly, the irritability of the patient, in relation to constitution, sex, and age; thirdly, what may be termed the constitution of the affected eye itself, and the texture in it immediately inflamed. Thus ophthalmy is likely to be attended with great severity when it attacks plethoric individuals, in whom there has been for some time previously a great determination of blood to the head and eyes, or whose sight has been strained by looking at shining objects, or whose constitutions have been hurt by good living and hard drinking. Every severe ophthalmy runs through its first stage much more rapidly in weak, irritable subjects and children, than in robust individuals. It is also another remark made by Beer, that every inflammation of the eye, at all considerable, is generally of shorter continuance in gray or blue-eyed, than in dark or black-eyed persons; and in the same manner inflammation of the internal, sensible and tender textures of the eyeball always passes through its first stage more quickly than inflammation of the eyelids.

With respect to the *causes of ophthalmy in general*, as the disorder frequently affects the innermost parts of the eye, and, when severe, is attended with some risk of the loss of the organ, the annihilation of its functions, or the spoiling of some of its textures; and also, as inflammation is the most frequent complaint to which the eye is subject, it is important to learn, as far as possible, the causes which, either directly or indirectly, give rise to it.

The atmospheric air and light have a direct and powerful operation upon the eyes; and in order that the former may have no hurtful effect upon these organs, it should be pure; that is to say, its regular component parts should not be altered, nor blended with extraneous substances. The temperature of the air is likewise described by Beer as making a good deal of difference in the susceptibility of the eyes for inflammation, either a very warm or cold air being in this respect hurtful. The observation, however, is qualified with the admission, that the terms *warm* and *cold* have only a relative signification to individual circumstances. The effect of a blast of cold air on the eye in exciting inflammation is universally known, and needs no comment. It is an opinion of Beer, that the eye is much affected by the quantity of electricity in the atmosphere; and he says, that on this account, no experienced practitioner would undertake the extraction of a cataract during or on the approach of a storm.—(*B* 1, *p.* 65.)

Passing over many interesting observations made by Beer on the contamination of the atmospheric air by the admixture of other gases, and the injurious effect of this change upon the eyes, I come to his remarks on the operation of light upon these organs. Though light, he observes, is indispensable to the functions of the eye, it becomes pernicious when suddenly increased beyond what the organ can bear, so as to be a source of irritation. As a proof of this fact he cites an instance in which a young, plethoric, strong man, whose eyes had been for some time unavoidably strained by immoderate exercise of them, was suddenly attacked with a violent ophthalmy, while looking at an optical representation of the rising sun, and carried home in great agony. But with respect to the influence of light, Beer observes that every statement is to be received only in a relative sense; for the degree of light which would answer very well for the eye of an African, would destroy many European eyes; and the same light which is borne without inconvenience by the eye of an adult, would excite in the eye of a newborn infant the *ophthalmia neonatorum*, by which so many children are deprived of the most valuable of the senses in the first days of their existence. Beer farther explains, that the same degree of light produces a stronger or weaker effect, according to the greater or less irritability of the eye of the same person at different times, as we see exemplified in every individual in the tenderness of his eye to light when he first awakes in the morning. Light is also not hurtful to the eyes, merely according to its quantity; for the direction of the rays makes a great deal of difference, the eye being less capable of bearing them with impunity the more they recede from a perpendicular line, and strike the organ slopingly or horizontally. Much likewise depends upon the kind of light; that which is reflected from a scarlet surface, being even more prejudicial than the sunshine which is reflected from a country covered with snow: another convincing proof that the bad effects are not always in proportion to the quantity of rays. The light of burning-glasses, concave mirrors, white screens, the full moon, &c., and the shining of diamonds, are well known to render the eyes weak, and prone to inflammation. Among other occasional causes of ophthalmy, Beer enumerates the custom of washing the eyes immoderately with cold water, a remark in which I do not place much confidence myself; the application of various stimulating medicated substances to them: compresses and band-

ages; the badness of instruments employed in operations upon the eyes; the employment of spectacles unnecessarily, or of such as are not adapted to the eyes of the individual; and every immoderate exertion of the eyesight.

But among the most important and frequent exciting causes of ophthalmy, are extraneous bodies, which insinuate themselves between the eyeball and eyelids, and every kind of wound or injury of the eye.

Foreign bodies liable to enter under the eyelids are of three kinds; first, such as are in themselves completely innoxious to the eye; or such as are likely to hurt the eye only when strongly pressed upon by the spasmodic closure of the eyelids, or by the patient's imprudently rubbing the eye; or they may be of a quality which injures the eye the moment they come into contact with it. Foreign bodies of the first description lie loose under one of the eyelids, and for the most part, either immediately behind its edge in the groove destined for the conveyance of the tears, or else in the fold, seen when the eyelid is everted, exactly at the line where the palpebra and sclerotic conjunctiva join together. They never actually lodge in the coats of the eye; but they irritate it mechanically, or chemically or in both ways together, according to their size, shape, and chemical properties.

In the list of such extraneous substances are inverted eyelashes; particles of dust; snuff; pepper; minute insects; and other small things generally carried under the eyelids by the wind.

As these foreign bodies are all of them more or less irritating to the eye, they must be considered as a principal exciting cause of ophthalmy, which frequently follows their entrance under the eyelids with extraordinary rapidity. However, the redness and effusion of tears sometimes instantly following the insinuation of extraneous substances under the palpebræ, and as suddenly ceasing on their removal, Beer considers rather as preliminaries to inflammation, than as this disorder itself.—(*B.* 1, *p.* 92.)

Wounds and other injuries of the eye, regarded as causes of ophthalmy, Beer divides into three kinds; viz. *mechanical*, *chemical*, and *mixed*. A prick of the eye with a fine needle is an example of a simple mechanical injury; the action of quicklime upon the organ is an instance of one purely chemical; and the violent propulsion of a red-hot bit of iron against the eye is a lesion which may be said to be both mechanical and chemical. The same author makes a variety of original reflections upon the differences connected with the extent and intensity of such injuries. Their intensity he views only as something relative; thus, either the force with which the eye is injured, is of itself too great ever to be resisted, as is seen in a gun-shot wound; or the organic powers of the patient are, from age, sex, or constitution, much too feeble for the eye to bear favourably any considerable injury, as is the case with children, and weak unhealthy females: or the organization of the eye itself may be weak, and the effects of the violence therefore greater, as exemplified in the fact of a brown or black eye generally bearing a wound better than a gray or blue one; or, lastly, the organic powers of the texture of the eye immediately injured may be too feeble to bear even a slight lesion, as is the case with the retina.—(*B.* 1, *p.* 95.)

Mechanical injuries of the eye may be made either with sharp or obtuse bodies. Sharp-pointed and cutting instruments are capable of readily penetrating the eye, without occasioning at the moment of their entrance, any violent compression or laceration of the neighbouring textures; and consequently the injury inflicted is a simple puncture, or an incision. Sabre-cuts of the eye, however, are to be excepted; for though the weapon may be sharp, the blow is always attended with more or less concussion, and injury of the textures adjoining the wound, which are very delicate and readily spoiled. Blunt weapons or bodies can only enter the texture of the eye by dint of great force, and, in this case, always cause a serious degree of compression, stretching, and laceration; but sometimes, when they do not penetrate the organ, the contusion is such as is productive of not less mischief.

In the case of a simple puncture or incision of the eye, Beer seems to think, that the subsequent ophthalmy is generally more owing to the incapacity of the wounded organ to bear the effects of the light, air &c. than to the injury itself abstractedly considered. He observes, that a proof of the truth of this opinion is seen in the extraction of the cataract; for if the operator is careless in the operation itself, opening the flap of the cornea very wide, so as to let the atmospheric air have free access to the inner textures of the eye; or if, after the operation is finished, he do not apply the dressings with caution, and properly darken the patient's chamber, he is letting the eye be subjected to some of the most active causes of inflammation. But though Beer is unquestionably correct, in regard to the injurious effects of light on the wounded eye, it may be doubted whether his theories do not make him attribute too much to the irritation of the air, and too little to the mechanical division of the parts.

Passing over many of Beer's observations on injuries of the eye produced by blunt bodies, and substances acting chemically upon it, I leave the topic of the direct exciting causes of ophthalmy, and come to the consideration of those which he regards as *indirect*. And the first to which he adverts is every thing that has a tendency to keep up a determination of a large quantity of blood into the vessels of the head and eyes. Immoderate bodily exercise, violent emotions of the mind, injudicious clothing, and high living are afterward enumerated as having an indirect effect in the production of ophthalmy: but it does not appear to me, that Beer's sentiments upon these points are entitled to much attention. With respect to *infection* and *contagion* as causes of inflammation of the eye, Beer understands by *infection* what at first takes effect only upon a small point of the body, but never upon the whole animal economy directly, that is to say, before absorption has taken place. Hence, says he, infectious diseases are very seldom the cause of ophthalmy, unless some of their matter be applied immediately to the eye itself; but he admits that they often dispose this organ to inflame from slight causes, by the impairment which they produce of the general health. On the other hand, he considers all *contagions* as very quickly affecting the whole of the constitution, directly through the medium of the skin, or the trachea, lungs, œsophagus, &c. Hence, contagion is set down as being much more frequently than infection the indirect cause of ophthalmy. Beer conceives, however, that as the contagious principle is blended with the atmosphere, it may also have an immediate operation upon the eyes, and thus he attempts to account for the organs not unfrequently exhibiting a tendency to inflammation at the very moment of the contagion taking effect. —(*B.* 1, *p.* 121.) But this is a difficult and obscure subject, which can be viewed to more advantage, when particular kinds of ophthalmy are considered.

In Beer's general observations on the treatment of inflammations of the eyes, the first indication specified, is *to remove immediately every thing which is obviously producing an irritating effect upon the eye, and to take care that no fresh source of irritation to the organ incidentally take place.* And as it frequently happens, even in healthy, strong individuals, that ophthalmy is occasioned by foreign bodies, either lodged under the eyeballs, or inserted in some part of the eyeball, and not suspected to be there, the earliest attention should always be paid to their gentle and skilful removal. Easy as this object is of accomplishment when not delayed, when the eye has not been seriously irritated by friction and pressure, and the patient is not of a weak, irritable constitution, it is often attended with great difficulty under one or the other of these circumstances, especially the last. In this case, strong convulsive rotations of the eyeball, followed by a violent and obstinate spasmodic closure of the eyelids, render it impossible to separate them; and the spasm is the stronger and more lasting, the more the extraneous substances are calculated, by their shape and chemical quality, to irritate the eye; and the greater the irritability of the patient is. In this state of things, every attempt forcibly to open the eye, or to examine it in the light, is not only useless, but increases and keeps up the spasm, which nothing will lessen and shorten, except darkness and perfect repose. But as timid, irritable persons are exceedingly apprehensive of the consequences of the lodgement of extraneous substances in the eye, the surgeon should endeavour to lessen their inquietude, by assuring them that every thing will be right again, which is strictly true, when the foreign

bodies are of the first class. Then the spasmodic closure of the eyelids will cease, and the extraneous substance admit of being properly taken away.

Success, however, does not always attend this simple method; for in very weak subjects, the spasm of the orbicularis palpebrarum is so violent and obstinate, especially when a foreign body lodges in the eye, and at the same time mechanically and chemically irritates it (as is the case with particles of snuff), that it becomes indispensable to have recourse to medicinal applications. For this purpose, Beer's experience has convinced him, that the best thing is a bread poultice, made either with milk or water, and containing some of the vinous tincture of opium. Care is to be taken, however, never to let it become quite cold during its application; for then the spasm would only be aggravated by it; and if such spasm has been of long continuance, when the surgeon is first sent for, the poultice, according to Beer, may be rendered more efficacious by the addition of hyoscyamus to it. In very irritable, hysterical, and hypochondriacal persons, such local treatment alone is frequently insufficient, and recourse must be had to the internal exhibition of antispasmodic anodyne medicines. At length, when the spasm of the orbicular muscle is so far diminished that the eyelids can be effectually opened without any force for the extraction of the foreign body, great caution and gentleness will yet be necessary, and, in particular, the eye should be kept in a very moderate light, as the spasm would be immediately excited again, either by sudden exposure of the eye to too much light, or rough handling of the eyelids.

Sometimes a person rubs his eye at first awaking in the morning, and if the eyelashes are very numerous and rigid, one of them will lodge between the eyeball and lower eyelid: it may readily be taken away with the end of a fine moist sponge or camel-hair pencil, the eyelid being depressed as much as possible, and the eye itself turned upwards, so that the hair may not be concealed in the fold of the conjunctiva. When the hair is situated under the upper eyelid (which Beer says rarely happens), it always lodges in the fold of the preceding membrane, whence it may be extracted in the manner above directed, with the difference that the eyelid must be raised or everted, and the eye rotated downwards.—(*Lehre von den Augenkr. b.* 1, *p.* 128—130.)

For directions respecting the treatment of redundant and inverted ciliæ, see *Distichiasis* and *Trichiasis*.

Small globular smooth extraneous bodies, lodged under the eyelids, are very easily extracted, when the eyelid is gently taken hold of both by its edge and the eyelashes, and lifted up from the eye, while the patient inclines his head forwards and the eye is turned completely downwards; the effusion of tears excited by these manœuvres will now generally wash these extraneous substances out of the eye, as they are not at all fixed. When the fissure between the eyelids is wide and open, but the eyeball at the same time very prominent, the object may also be easily accomplished, when the upper eyelid is gently and repeatedly stroked with the finger from the outer towards the inner canthus; in which case, the round smooth foreign body soon makes its appearance above the caruncular lachrymalis, whence it falls out of itself, or may be taken with the corner of a pocket handkerchief.

The worst cases are those in which the eyes are very prominent, and the fissure of the eyelids small, as all the above methods are then useless, and only productive of irritation. In this circumstance, therefore, Beer recommends the surgeon to take hold of the eyelid by the ciliæ and its edge with the thumb and fore-finger, and separate it from the eyeball, which is to be turned downwards, while, with Daviel's small scoop, or the head of any large curved needle, introduced straight under the eyelid, at the outer canthus, as high as possible, the extraneous substance is to be extracted with a semicircular movement, directed towards the nose.

Instead of this painful, irritating plan, I recommend the eyelid to be simply everted by taking hold of the ciliæ, and drawing them forwards and upwards, while a probe is used for pressing back the upper portion of the tarsus. The foreign body may then be plainly seen, and easily removed.

Particles of common dust, and of the sand and powders frequently thrown over letters, are very apt to get into the eyes of persons who open their letters carelessly, or from short-sightedness are obliged to bring them close to the nose, are generally more difficult of extraction. In the attempt, however, the eye must never be subjected to too much irritation. According to Beer, these extraneous particles of dust or sand may sometimes be removed by washing the eye well, or by dropping into it milk, or some other viscid fluid, while the patient lies upon his back, and the eyelid is lifted up from the eye. But the most expeditious and certain plan is to employ a syringe, the pipe of which is to be introduced under the upper eyelid near the outer canthus, and the fluid thrown briskly in the direction towards the nose. If all the extraneous matter cannot be thus removed, the rest may sometimes be taken out, if the eyelid be everted in the manner above directed, which seems to me the right method to be adopted in several cases, for which Beer recommends other proceedings.

When particles of sugar, or other soluble, not very irritating substances, happen to insinuate themselves into the eye, professional aid is seldom requisite, as they generally dissolve in the tears, and are voided before a surgeon can arrive. Snuff, pepper, and other minute irritating bodies, as well as small winged insects, are to be removed in the same manner as particles of dust and letter-sand; but particular care is to be taken afterward to wash the eye well with some lukewarm mucilaginous collyrium, until the irritation caused by the chemical effect of such foreign bodies has been completely obviated.

The removal of foreign bodies of the second class is usually attended with more difficulty, because they, as well as those of the third class, more frequently produce a violent and obstinate spasmodic closure of the eyelids, and are seldom loose, being generally fixed in the cornea. However, when they happen to be detached, they may be extracted in the same way as small round smooth extraneous bodies, except that the stroking of the eyelid with the finger should be omitted not only as useless, but likely to press any of these substances, which are of a pointed shape, into the loose conjunctiva, so as to injure the eye itself, which would otherwise not be hurt. The nibs of pens, the parings of the nails, and small hard-winged insects, when lodged in a depression of the cornea, or white of the eye, Beer says, may be easily dislodged by means of a small silver spatula. Other foreign bodies of the second class are not only fixed in a depression, but even penetrate more deeply than the conjunctiva; and in old subjects in particular, they often insinuate themselves into the loose cellular membrane under the conjunctiva in the white of the eye, partly in consequence of the convulsive motions of the eyeball and eyelids, and partly by reason of the attempts made to loosen them. Hence, they frequently become situated a great way from the place of their entrance, and are completely covered by the conjunctiva. But even when they lie immediately in the wound, they are so intimately connected with the subjacent loose cellular membrane of the conjunctiva, that every attempt to remove them with forceps is not only unavailing, but hurtful to the eye, inasmuch as the injury is thereby rendered deeper. They may be taken away with facility, however, when lifted up with a pair of small forceps, and cut away with a pair of scissors, together with the piece of cellular membrane with which they are directly connected. If such extraneous substance should be actually underneath the sclerotic conjunctiva, Beer recommends the eyelids to be well opened, and the eye to be brought into a position, in which the part of the conjunctiva covering the foreign body is rendered tense, when an incision is to be made with a lancet down to the extraneous substance, which is to be taken hold of and removed with a pair of scissors, the assistant being careful to keep hold of the eyelids during the operation. On the other hand, when the foreign body is actually lodged between the layers of the cornea, Beer considers that its extraction may be best accomplished with a lancet-pointed couching needle. But whatever instrument be used, its point must be passed with great caution closely and obliquely under the foreign body; and care must be taken not to introduce it too deeply, lest the anterior chamber be opened, which may readily happen in young subjects; and when it does, the aqueous humour flows out, and the cornea becomes so flaccid, that the removal of the extraneous substance is quite impracticable, before the puncture has healed, and the anterior chamber is again distended

The removal of foreign bodies of the third class mostly demands very great caution; first, because, as Beer observes, no particles of them should be allowed to remain in the eye, which, without the utmost vigilance, is apt to be the case; and secondly, because the wound of the eye, already considerable, should not be made larger than can be avoided. The extraction of small bits of glass is particularly difficult, as they cannot be seen, but must be found out entirely by the feelings of the patient, or the *tactus eruditus* of the surgeon assisted with a probe. When in this way a particle of glass is detected, Beer directs us to take hold of it with a pair of forceps, and cut it away with scissors. The place from which it has been removed must then be carefully probed, in order that no other fragment may be left in it.

According to the same author, pieces of iron and steel, which strike the eye so forcibly as to enter it, as well as all other fragments of metals, which are readily oxydated, should be as carefully removed as bits of glass; for the more easily they combine with oxygen, and the longer they remain, the more brittle they become, and the more apt are minute particles to be left in the eye, especially in the cornea. A speck on the part of this membrane where the splinter has lodged, is the least serious consequence of such an event. When fragments of steel which have quite a black appearance remain fixed in the cornea several hours, it is found, after their removal, that the whole circumference of the depression, from which they have been extracted is of a reddish-brown colour, produced by the rust left behind, and firmly adhering to the cornea. Every particle of rust must be carefully removed with a couching needle, or else a permanent speck will ensue; but caution must be used not to puncture the anterior chamber. The extraction of particles of lead and gunpowder is generally difficult, as they have mostly been projected with great force against the eyelids, so as to produce not only a great deal of spasm, but instantaneous swelling of those parts. Hence, Beer says, that they should commonly be taken hold of with forceps and cut away. Particles of cantharides are easily removed with a small silver spatula, or the end of an eye-probe; but their violent chemical effect must be obviated, by frequently applying to the part a little fresh butter, touching it with a camel-hair pencil dipped in diluted liquor ammoniæ, or dropping into the eye lukewarm mucilaginous collyria.

The attempt to wash particles of quicklime, mortar, &c. from the eye, Beer says, only has the effect of rendering their violent chemical operation more diffused, and he recommends them to be taken out by means of a fine hair-pencil, dipped in fresh butter or oil. This is the only way of immediately counteracting their chemical effect; and after their extraction, the application of unctuous substances to the part should still be continued.

The stings of small insects, when lodged in the sclerotic conjunctiva, are often very difficult of detection; but they are more readily seen on the skin of the eyelids. Beer directs us to remove them with a pair of forceps, or a couching needle, and then to have recourse to means calculated to diminish the ophthalmy, which, in these cases, always begins on the first occurrence of the accident. Small shots lodged in the loose cellular texture of the conjunctiva must be cut out. In general, says Beer, it is necessary to divide the conjunctiva, as they are mostly situated some distance from the place of their entrance, and of course are quite covered by that membrane.

As soon as a foreign body has been extracted from the eye, all precursors of ophthalmy diminish; as, for instance, the redness, intolerance of light, and the increased secretion and effusion of tears. Even the inflammation itself, when already developed, subsides; but this affection is slight, if the eye has not itself been injured by the extraneous body. On the other hand, when the eye has suffered more or less irritation from the nature of the substance itself, and the treatment requisite for its complete extraction, the inflammation may become more severe, unless the surgeon pay immediate attention to the injury left on the eye.—(*Beer.*)

According to the principles laid down in the foregoing columns, the first indication in the treatment of wounds of the eye in general is, to remove every kind of extraneous substance which may impede the cure. Hence, the necessity of observing whether the instrument with which the wound has been inflicted, or any part of it, is lodged in the eye. When this is the case, the foreign body should be quickly extracted, or else no recovery of the organ can take place. But, says Beer, this is more easily said than done; for, in many instances it is very difficult to find and remove the fragments of instruments, on account of the great delicacy of the organ, the irritability and alarm of the patient, and the bleeding from the part. However, the attempt must be made with the greatest gentleness possible; and Beer particularly advises a fine elastic whalebone probe to be used, instead of a silver one, for the purpose of detecting the fragment. He also sanctions making an incision, for facilitating the finding of the extraneous substance, provided it is certainly lodged, and cannot otherwise be traced. This author attaches great importance to the fulfilment of this first indication in all wounds of the eye, and relates a case, to which he was called, where a piece of tobacco-pipe had been driven so forcibly and deeply at the external canthus between the eyeball and orbit of a young student, aged 19, and of delicate make, that the eye was immediately pushed out of its socket, and on Beer's arrival it lay with the cornea quite against the nose. Its very position led Beer to suspect, that some extraneous body was lodged in the orbit; and notwithstanding the assurances of all the bystanders to the contrary, and the patient's being affected with violent spasms, the part was examined with a fine flexible whalebone probe, by which means a piece of the pipe, nearly an inch in length, was felt, and immediately extracted with a pair of forceps. Scarcely had this substance been removed, when the eyeball was spontaneously drawn back into the orbit, though with the cornea still turned towards the nose, and the twitchings of the muscles also instantly ceased: but the eye was blind, and had but a very faint perception of light. By very careful treatment, the eyesight was restored in five weeks; but the eye could not turn towards the temple, owing to the considerable injury, which the external straight muscle had sustained. With the aid of electricity, the power of rotating the eye about half its natural extent outwards was in the end regained, and the remaining infirmity resisted every method deemed worthy of trial.—(*Beer, b.* 1, *p.* 146. See *Exophthalmia.*)

Fragments of broken instruments are not the only kind of extraneous substances which may lodge in the wounded eye: for, as Beer observes, when the injury is extensive, contused, and lacerated, there may be splinters of bone, or pieces of membrane, cellular substance, muscle, &c. so detached as to be quite incapable of reunion; on which account, this author sets them down as foreign bodies requiring to be taken away. However, I conceive that with respect to the soft parts, the advice here delivered should be received with much limitation.

Wounds of the eye, like those of most other parts of the body, may be healed either by direct union, or a slower process, in which suppuration, the filling up of the chasm by granulations, and the gradual, but not complete, approximation of its edges to each other, are the most conspicuous effects. Clean incised wounds may be cured in the first way (see *Cataract*); and lacerated, contused wounds, or such as are attended with loss of substance, in the second. But whichever plan be attempted, the eye must be kept quiet, and excluded from the air and light, with a light suitable bandage. As in wounds and chemical injuries of the eyeball itself, not admitting of reunion, the eyelids, when closed, completely cover the wounded part, the application of dressings to it becomes both unnecessary and impracticable, and all that can be done is to drop frequently into the eye a mucilaginous collyrium, and cover the organ with a light bandage, which will not make any hurtful pressure. In simple contusions of the eye, unaccompanied with wound, Beer deems a bandage the only requisite application; but when these accidents are conjoined with effusions of blood, he recommends the use of spirituous aromatic fomentations, with the view of promoting absorption.

In healthy individuals, small punctures of the eye, made with instruments like needles, and perforating only the conjunctiva, or cornea, but not reaching the deeper textures of the organ, are generally followed by no serious consequences, even when all the aqueous humour is voided. It is only necessary to keep the eye quiet, and the air and light excluded from it by means

of a light compress, suspended over it from the forehead. Under this treatment, such punctures are so firmly closed in twenty-four hours, without any opacity, that the chambers are nearly filled again with aqueous humour, and the intolerance of light, which was only the effect of the loss of that fluid, is entirely removed.

In large clean cut wounds of the eye, whether accidental or made in the extraction of the cataract, the prognosis must be very cautious, and the treatment conducted with the utmost care; for, says Beer, it too readily happens, that though the wound is not important in itself, its effects become from the least mismanagement highly dangerous to the eye. Hence, when the patient is known to be either an individual not likely to take proper care of himself, or one too much alarmed about the fate of his eye, the prognosis should be very guarded, even where the constitution is of the best description, because a violent and dangerous attack of ophthalmy is apt to ensue, and destroy the eye sooner than effectual succour can be administered. On the other hand, when the patient is steady and intelligent, and the case is properly treated, the prognosis is very favourable.

In considerable cuts of the eye, it is only possible to promote their union with a suitable bandage, and by effectually preventing all motion of the eye and eyelids, which is best accomplished when the sound as well as the injured eye is covered, and the patient kept quiet in bed until the sides of the wound have grown together.—(*Beer, b.* 1, *p.* 164.)

As cases of deeply-penetrating wounds of the eyeball itself, Beer enumerates the punctures made in the depression and reclination of the cataract, and in every mode of forming artificial pupils; lacerations of the conjunctiva with ears of corn, pointed pieces of iron, splinters of wood, &c. In these cases, the prognosis, he says, is always very favourable, when the patient can put himself under all the conditions which the treatment requires, and his constitution is good. The first thing here to be carefully fulfilled is, the removal of any fragments of the instrument or body with which the injury has been inflicted; and it should be recollected, that in these cases, minute splinters, which are scarcely discernible, frequently lodge in the conjunctiva, and, if not immediately traced and removed, produce the very worst consequences. By the weapon being suddenly withdrawn, pieces of the conjunctiva are sometimes nearly torn away, and hang from the eye; these Beer directs to be cut off with scissors. The best applications, he says, are either lukewarm mucilaginous lotions, or (when blood is effused under the conjunctiva) vinous spirituous collyria. To these cases, he thinks fomentations scarcely applicable. When the quantity of blood effused in the loose cellular texture under the conjunctiva is very considerable, he recommends scarifications; but where this practice does not seem likely to answer, and vinous spirituous collyria are ineffectual, some of the liquor ammoniæ should be added to them. When any fragment of the instrument has been overlooked, and remains in the part, either a copious suppuration ensues, and the fragment is at length detached, or else in a patient of inferior sensibility, a soft, spongy, readily bleeding, pale-red excrescence is formed all round the extraneous body, and sometimes even projects between the eyelids. Here, according to Beer, the first requisite step is to cut away the fungus with a knife, so as to reach the irritating fragment under it, and then the rest of the excrescence may be removed by touching it with the tinctura thebaica, or vinous tincture of opium.

With respect to lacerated wounds of the cornea, they either penetrate the anterior chamber, or not. They are all of them attended with more or less concussion, laceration, stretching, and partial contusion, of the delicate anterior textures of the eyeball; a consideration, as Beer observes, materially affecting the prognosis. When in such injuries of the cornea inflammation and suppuration cannot be prevented, or the discharge is protracted, an obvious scar is always the consequence, which, when situated in the centre of the cornea, is a serious impediment to vision. Every endeavour should therefore be made to unite the wound by the first intention; and the best chance will be afforded by treating the eye precisely in the same manner as after the extraction of the cataract.—(*See Cataract.*) And when the plan fortunately succeeds, the flow of the aqueous humour out of the eye ceases in about 36 or 48 hours, and the anterior chamber becomes distended again; but the site of the injury continues visible for some time afterward. The speck, however, ultimately disappears, though much sooner in young, healthy subjects, than in the aged and feeble. When the opacity does not go off of itself, Beer finds a collyrium, containing some of the lapis divinus (*see Lachrymal Organs*), and the vinous tincture of opium, the most effectual means of dispersing it. Through large wounds, penetrating the cornea near its edge, a fold of the iris is apt to protrude, and when it does, it should be replaced, which can only be effected without mischief to the eye by gently rubbing the upper eyelid, and then letting a strong light suddenly strike the organ. In this case, the employment of instruments is considered by Beer highly objectionable. When the iris is not immediately reduced, it, as well as the cornea, is attacked with inflammation, and soon becomes firmly adherent to the edges of the wound.—(*See Iris, Prolapsus of the.*)

Large wounds penetrating the eyeball, and reaching the iris, are always of a very serious nature, even though the latter part may have received only a prick, or cut, because as the injury has been produced by accident, and not by art, the wound of the iris cannot be free from all laceration and contusion. It is incredible, says Beer, what extensive injuries the iris will bear in healthy individuals at its pupillary and ciliary edges, especially when produced by very sharp instruments; nay, rents may happen at both its edges, without any ill consequences, if the constitution be favourable: a proof of which fact is seen in the two common methods of forming an artificial pupil, viz. the excision of a piece of the iris, and the detachment of the iris from the ciliary ligament, as practised both by Schmidt and Scarpa. But, according to Beer, all violent pressure, or actual contusion, particularly when it affects the portion of this organ between its two circles, cannot be borne even in the best constitutions, and the least grievous consequence is inflammation, soon followed by a partial, or complete closure of the pupil, or suppuration in the eyeball. When the instrument causing such injury passes to the iris through the cornea, as is mostly the case, and the wound in the latter tunic is extensive, the torn iris is frequently pulled between the edges of the wound, at the moment when the weapon is withdrawn, and protrudes in a lacerated state. In this case, Beer recommends the torn projecting piece of the iris to be cut away with scissors close to the wound in the cornea, when the rest, he says, is generally retracted within the eye. Thus, an adhesion of the iris to the cornea, termed *synechia anterior*, may often be prevented, which, when the lacerated iris is suffered to hang out of the cornea, is inevitable, surrounded by a large opaque cicatrix.

Some violent blows on the eye, though they cause no wound, are attended with such a concussion of the anterior hemisphere of the organ, that more or less of the iris is instantaneously separated from the part of the ciliary ligament where the force is most vehement. The consequence of this accident is either a double pupil, or the natural pupil closes, and the artificial one remains open. Such injuries may be produced by the lash of a whip, or a horse's tail (a common accident in the narrow streets of Vienna), or the thrust of any bluntish weapon against the outer part of the cornea; and they are purposely inflicted in the method of forming an artificial pupil, recommended both by Schmidt and Scarpa.

Wounds which enter the eye through the sclerotica near the cornea usually produce a considerable effusion of blood in the chambers of the aqueous humour; but Beer thinks, that there is never any necessity for making an opening for its discharge at the lower part of the cornea, except when it is so considerable as completely to hide the iris, at the same time that the eyeball is affected with very painful tension and hardness. In all wounds of the iris it is likewise proper to follow the same treatment as applies to penetrating wounds of the cornea, with this difference, that when the effusion of blood in the chambers of the eye is considerable, the action of the absorbents should be promoted by the immediate employment of vinous aromatic collyria, and afterward warm spirituous lotions.

Wounds of the eyeball affecting the corpus ciliare are set down by Beer as extremely dangerous, inde-

pendently of the inflammation which quickly follows. However, such injuries are most serious when they consist in a real contusion or laceration of the corpus ciliare, which can hardly take place without a severe concussion or actual disorganization of the retina, and laceration of the principal ciliary nerves and vessels. Hence, besides an effusion of blood in the chambers of the aqueous humour, a partial or complete amaurotic blindness is instantly produced, and the iris in the vicinity of the place where the instrument entered is so retracted towards the margin of the cornea, that neither of its circles can be seen. In cases of this description, it also frequently happens, says Beer tha the patient, or the person who inflicted the wound, suddenly and roughly pulls the weapon out of the eye again, and together with it a part of the corpus ciliare, which is then to be regarded as an extraneous substance, and immediately cut off. With respect to the prognosis and treatment, the observations already made on these topics in reference to wounds of the iris are here quite applicable; excepting that, as the effused blood is less copious than in the latter cases, there can never be here any necessity for letting it out by a depending opening in the cornea.

Wounds of the eye affecting the crystalline lens are not unfrequently followed by the formation of a cataract, and so are blows on the eye, which may be supposed to produce this effect by destroying some of the minute nutrient vessels naturally connecting the capsule with the lens.—(*Beer, b.* 1, *p.* 218. The treatment of these accidents resembles that of injuries of the iris, except that the surgeon has rarely any extravasation of blood to deal with. However, when the lens has slipped into the anterior chamber, Beer recommends its immediate extraction through an incision in the cornea, in order to prevent the eye from being destroyed by a violent attack of traumatic inflammation and suppuration. Nor when inflammation has come on should this measure be postponed, as Beer has constantly found the disorder lessen after the lens has been taken out.

Considerable wounds of the eye, attended with loss of the vitreous humour, are described by Beer as of a very serious nature; but they rarely take place accidentally, being almost always the consequence of a surgical operation. Accidental injuries of this kind are generally combined with so large or complete a discharge of the vitreous humour, and with such mischief to the organization of the eye, that the consequence is a loss of the eyeball, or such a dwindling of it, that the fissure of the eyelids becomes nearly closed. According to Beer's experience, injuries of the foregoing kind, arising from accident, are mostly produced by the horns of cows. On the contrary, the effusion of the vitreous humour in operations upon the eye, he observes, is seldom followed by the loss of vision. Kortum, in his Manual on the Diseases of the Eye, adverts to some instances which he had seen, or fancies that he had seen, where *the whole of the vitreous humour was lost*, and yet the eyesight afterward became as strong as if no such accident had happened. On the other hand, Beer never met with any of these fortunate cases; but always found the sight seriously impaired when the quantity of vitreous humour lost amounted to nearly its half, and complete blindness the result when the loss much exceeded that quantity. He conceives also, that Kortum had probably seen but few cases of this nature, and therefore might have been mistaken as to the proportion of the vitreous humour discharged, which to the inexperienced seems larger than it really is, and he cautions surgeons not to promise too much in cases of this description.—(*B.* 1, *p.* 222. See *Cataract.*)

Considerable injuries of the eyeball, complicated with a concussion, bruise, or actual wound of the retina, produce either gradually or immediately an amaurosis, which is almost always incurable. When the concussion of the retina is less violent, and does not affect every part of this texture, it may occasion only an amaurotic weakness of sight. In worse cases the surgeon may think himself very successful, if he can prevent the figure of the eye from being destroyed by the subsequent inflammation, all idea of the recovery of the eyesight being out of the question. The treatment is the same as that commonly adopted after operations for the removal of an opaque lens (see *Cataract*); but there is one particular circumstance sometimes attending injuries of the retina and ciliary nerves claiming notice, viz. violent vomiting; a symptom which Beer says may even attend contusions of the sclerotica and of the ciliary nerves and retina, without any wound. Injuries of the ciliary nerves, he observes, are denoted by a very peculiar appearance; for, near the injured part, the iris is drawn up so close to the edge of the cornea, that its colour can scarcely be seen. When the surgeon is consulted in a case of this kind, though some inflammation may have commenced, the prognosis is yet favourable in regard to the preservation of the eye; for a gentle opiate will relieve the vomiting when merely a nervous effect, not depending upon the loaded state of the gastric organs; but if the case be of this last description, the primæ viæ should first be emptied. However, when a traumatic inflammation is completely established before the treatment is begun, the eye is generally destroyed, as the repeated and violent vomitings cause a great determination of blood to the head and eyes, and increase of the inflammation; an effect which the opiates given for the relief of the vomiting also tend to produce.

Beer has seen two cases in which the eye was picked with a needle near the insertion of the external straight muscle into the sclerotica: in both instances the punctures were so small, that they would scarcely have been found, had not the patients known their situation exactly by the pain, and they were then only perceptible with a magnifying-glass. The punctures were soon followed by a convulsive rolling of the eyeball, and afterward by trismus, which continued severe in one patient a day and a half, and in another two days, but yielded to large doses of musk and opium given at short intervals, the warm bath, and the application of warm poultices containing hyosciamus.

As chemical injuries of the eye produce an actual loss of substance, they are even more serious than common mechanical lesions. However, chemical injuries of little extent are generally repaired with tolerable facility and expedition. Quietude of the organ, and moderating the outward noxious effects by lukewarm mucilaginous applications, either in the form of fomentations or eye-waters, are the only requisite measures. If the cornea itself be hurt, as frequently happens when boiling-hot fluids strike the eye, a kind of vesicle appears on the injured part, which becomes more and more white. The vesicle either bursts of itself, or subsides without breaking. In both cases the production of the conjunctiva, of which the cyst of the vesicle is composed, shrivels up and peels off, a new membrane of a similar nature being regenerated underneath. An opaque speck is frequently apprehended; but, says Beer, if the surgeon will merely avoid being too much in a hurry to open the vesicle, and not disturb the work of nature by applying various remedies to the eye, there will be no danger of such an occurrence.

More extensive chemical injuries of the eye, which at first are not in themselves very severe, frequently become dangerous, in consequence of care not being taken to prevent the influence of external stimuli. To this class of cases belongs the accidental sprinkling of the eye with boiling fluids or strongish mineral acids. And even in these examples, says Beer, the prognosis is not unfavourable, and a complete recovery may be effected, when the treatment is conducted according to the directions already given with respect to such accidents in general. While this author approves of cutting away any substance which is dead and partially detached, he strongly cautions surgeons not to remove the thin layer of the conjunctiva, nor to puncture any vesicle which may form.

When the burning or corrosion is not limited to the nonjunctiva of the eyeball, but extends to the lining of one or both eyelids, Beer recommends covering the injured parts with mucilaginous applications and mildly astringent ointments, containing tutty or the white oxyde of lead. In these cases, keeping the eye perfectly motionless must be hurtful, as it tends to promote the formation of adhesions either between the eye and eyelids (Symblepharon), or between the eyelids themselves (Anchyloblepharon).

Extensive deeply-penetrating chemical injuries of the eyeball, Beer describes as being almost always followed by more or less impairment of the functions of the organ, or of some of its particular textures; because such accidents never happen without a loss of substance. Thus a part or the whole of the cornea may

be entirely destroyed, as in injuries caused by quicklime; and frequently adhesions between the eye and eyelids, or between the two latter parts, cannot be prevented by any kind of skill.—(*Beer.*) These serious degrees of mischief, as the same author observes, are mostly occasioned by slaked or unslaked lime, concentrated mineral acids, fire, &c. Unslaked lime, especially when extensively diffused over the eye by the immediate application of water, not unfrequently produces a sudden destruction of the whole of the cornea, which is changed into a grayish, pappy substance, capable of being removed from the subjacent iris with a camel-hair pencil. Such an annihilation of texture, however, is generally restricted to particular points, or the surface of the cornea. Wherever this membrane has been so much decomposed, that a manifest depression is directly perceptible in it, when inspected sideways, a snow-white shining speck must be expected to be the consequence. Slaked lime never operates upon the cornea with so much violence, usually causing (as Beer states) only a superficial corrosion, or a coagulation of the lymph between the layers of the cornea. Nor are mineral acids, even when concentrated, generally so destructive to the cornea as quicklime: first, because, as fluids, they do not long remain in contact with the eye; and secondly, because the immediate mixture of the tears with them weakens their operation, whereas it only increases that of unslaked lime. The local treatment here consists in carefully removing every particle of the hurtful substance, afterward dropping frequently into the eye lukewarm mucilaginous decoctions or collyria, or covering the injured place with a mild cerate, and excluding the air and light from the eye. Every endeavour must also be made to prevent the formation of adhesions between the injured surfaces.

In very severe burns of the eyeball, of course, all idea of restoring its functions is out of the question. The violence of the injury is the greater, the more numerous the vesicles are upon the conjunctiva, and the more the eyeball and the iris are incapable of motion. Here the only indication is to moderate the inflammation, and avert such additional mischief as might otherwise be produced by it. With this view, the eye should be kept at rest, and excluded from the light and air. According to Beer, the most common injuries of the eye, partaking both of a mechanical and chemical nature, are those caused by mortar, or the accidental touching the eye with hot curling-irons. When the mortar contains no particles of quicklime, it often occasions, at particular points of the cornea, very white specks, which Beer describes as being composed of congulated lymph, and admitting of dispersion. He even declares, that when the whole of the cornea is in this state, its transparency may be restored by proper treatment, as has been frequently exemplified to the gentlemen attending his clinical lectures.—(*B.* 1, *p.* 234.) The pricking of the eyeball with a red-hot needle, and the stinging of it by bees, wasps, and other insects, are also both chemical and mechanical injuries. Whether the sting be left in the skin of the eyelid, or in the conjunctiva, or not, a considerable inflammatory swelling immediately takes place; and if the sting be lodged and not now taken away, the inflammation spreads, and the eye itself is endangered. In two cases, where the stings of bees were left in the skin of the upper eyelid, Beer has known gangrene arise in the short space of a day and a half, and the patients were saved with great difficulty. The treatment of such cases consists in immediately extracting the sting, if lodged, and applying folds of linen over the eye, wet with cold water.

After noticing the destructive effects of burning substances, the explosion of gunpowder, and fulminating silver on the eye (cases in which, when the functions of the organ are annihilated, the only indication is to diminish the subsequent inflammation and its consequences), Beer inquires, what is the reason why the slightest mechanical or chemical injuries of the eye in an apparently healthy subject are sometimes followed by an immoderate degree of inflammation, and even the loss of the organ from suppuration? It is, says he, an observation made by Schmidt that there are some eyes which the greatest bunglers may abuse for hours at a time without being spoiled, their powerful organization defying all such unskilful disturbance; while other eyes are met with, which the most skilful operators can hardly touch without inducing a destructive degree of inflammation and suppuration. It was to this peculiar idiosyncrasy that Schmidt applied the term *vulnerability*. (*Verwundbarkeit*). Patients of this habit are said to possess an exceedingly fine soft skin, with a reddish polish upon it: and their cheeks are not only red, but exhibit a net-work of very minute vessels, which seem as if injected. Such individuals appear as if they were in the bloom of health; and, says Beer, in some respects they are really so. When their spirits are raised by the slightest causes, their complexion is universally reddened; but the least fear turns them as pale as a corpse. Their skin is described as being uncommonly irritable, sensible of every impression, and attacked with an erysipelatous redness whenever any fatty substance touches it. In such habits, the utmost caution is necessary whenever the eyes have been injured, and the prognosis should be reserved. And when an operation is to be done on their eyes, Beer recommends the previous exhibition of opium, and the application of a blister to some part of the skin, at a considerable distance from them. As a prophylactic measure, he also directs regular friction of the surface of the body.

In severe ophthalmies, particularly those which affect the eyeball itself, all mental emotions, anger, joy, &c. should be avoided. Hence, no talkative nor quarrelsome persons should be suffered to remain with the patient; and noisy children ought to be kept away from him. The apartment should be ventilated at least once a day, without the patient being exposed to any current of wind. All touching of the eye, or rubbing it with the bed-clothes during sleep, must be strictly prohibited. Stimulating, spicy food, spirituous drinks, and great bodily exercise, are likewise to be forbidden. In the list of things which have a hurtful effect, Beer also includes all exertions of the lungs, every kind of disturbance, an atmosphere impregnated with tobacco-smoke, &c.

Having fulfilled the first general indication by removing, if possible, every kind of irritation acting upon the eye, the *second general indication* specified by Beer as proper in the first stage of ophthalmy, is to be observed; which is, *to moderate, according to the degree of inflammation, the agency of several things to the effect of which the organ is naturally subjected.* Thus the inflamed eye should not be exercised, even though the eyeball itself may not be immediately inflamed; and the operation of the light and air should be diminished partly by green silk eye-shades and partly by window-blinds. Attention to this rule is still more necessary when the eyeball itself is affected With respect to the exclusion of light, it is to be well remembered, that it is only advisable, as Dr. Vetch observes, in the very early stage of inflammation, the eye becoming more irritable and less manageable, when the access of a moderate degree of light is afterward prevented.—(*On Diseases of the Eye*, *p.* 16.)

The *third general indication* mentioned by Beer, as proper in the first stage of ophthalmy, when the disorder threatens to extend to the whole organ, and to bring on a febrile disturbance of the system, is to counteract these effects by covering the eye with folded linen wet with simple cold water, or vinegar and water; and having recourse to leeches, or, when the nature of the case allows, to scarifications.—(*B.* 1, *p.* 242.) Here, however, it merits particular notice, that Beer, in expressing a general preference to cold lotions in the first stage of ophthalmy, differs from Richter, Scarpa, and Mr. Travers (*Synopsis of the Diseases of the Eye*, *p.* 250); all of whom, in the painfully acute stage, recommend tepid emollient applications.

With regard to leeches, the late Mr. Ware objected to their being put on or very near the eyelids, as they sometimes cause a considerable swelling of these parts, and increase instead of lessening the irritation. In ordinary cases, his method was to apply three on the temple, about an inch and a half from the outer part of the orbit. Scarpa recommends applying the leeches to the vicinity of the eyelids, especially about the inner canthus, on the vena angularis, where it joins the frontal, deep orbitar, and transverse vein of the face. Beer prefers nearly the same situation as that specified by Scarpa, viz. the inner canthus, immediately below the under eyelid; and he forbids the application of leeches above either canthus, as likely to produce a disagreeable ecchymosis in the cellular

membrane of the upper eyelid. The number of leeches, and the time which they should be allowed to suck, he thinks, ought to depend upon the severity of the inflammation. According to Beer, when this mode of bleeding is to be of any service, the patient will experience a considerable abatement of the throbbing pain, tension, &c. in the affected eye. Hence, when any of the leeches fall off prematurely, the bleeding from the bites is to be kept up with a sponge dipped in warm water, until such relief is felt. In the acute stage, Beer considers the abstraction of blood by means of scarifications rarely admissible.—(*B.* 1, *p.* 243.) By Mr. Lawrence it is decidedly condemned; and it is a method to which I never have recourse in my own practice. Mr. Travers also sets down scarifications of the conjunctiva as mostly objectionable in the acute stage; though highly beneficial in the chronic, where the lining of the eyelids is thickened and overvascular; and a considerable discharge of blood may be thus obtained, if the operation be briskly done with a sharp lancet, and the lower lid kept everted and fomented. The same gentleman states, that cupping has a decided superiority over leeches, but that both are well adapted to relieve local congestion. Yet he deems these methods too indirect to answer as substitutes for the lancet, where it is desirable to make the system "sustain and feel a reduction of power;" in which case blood must be taken from a vein or the temporal artery.—(*Synopsis, &c. p.* 249.) The taking away of blood by cupping the temples is considered by many modern surgeons a very efficacious plan; quite as much so as that of opening the temporal artery, the hemorrhage from which is sometimes difficult to suppress. While inflammation of the conjunctiva is described by Dr. Vetch, as not much affected by bleeding, unless the quantity of blood taken away be such as to occasion syncope, he states that the abstraction of blood in quantities proportioned to the violence of the symptoms, more especially by means of cupping and leeches, has for the most part sufficient control over the various states and individual symptoms of sclerotic inflammation. In some obscure cases of what this author terms amaurotic inflammation, he has seen great benefit derived from the application of leeches to the septum nasi; and he represents their being put directly on the conjunctival lining of the eyelids, as being sometimes more advantageous than on the adjacent integuments, the orifices bleeding with great freedom.—(*On Diseases of the Eye, p.* 15.)

The *fourth general indication* enumerated by Beer, is that which has for its objects a diet and regimen suited to the state of the case after it has attained a degree in which its effects begin to be felt throughout the system. When therefore the plan is to be rigorously practised, the patient's ordinary diet is to be reduced, and he is to be allowed only vegetable food, cooling drinks, water, weak lemonade, &c. And not merely the eye itself is to be kept at rest, but the whole body.

Should the disorder be farther advanced, and attended with a great deal of inflammatory fever, the observance of the foregoing indications will not suffice for checking the inflammation and preventing suppuration, unless the *fifth indication* laid down by Beer be fulfilled; which is, *to employ such remedies as operate upon the whole constitution.* 1. Purgative and gently aperient medicines, which will empty the bowels well, and lessen the determination of blood to the head and eyes. 2. Clysters, which are useful on the same principles. 3. The frequent exhibition of the nitras potassæ. 4. General bleeding, the efficacy of which will much depend upon the blood being voided in a full stream. Beer seems to prefer opening a vein on the foot; but in England the most experienced practitioners generally open a vein in the arm, and sometimes the temporal artery. The blood, as Beer remarks, should be allowed to flow until the hard small pulse rises and becomes plainly softer; for otherwise the operation will be completely useless. Also, when in these cases general bleeding is no longer indicated, the employment of leeches will yet be advantageous, and afterward scarifications may be practised, which, at an earlier period, would have aggravated all the inflammatory symptoms.

Respecting the *prognosis* and *indications in the second stage of ophthalmy*, Beer offers many interesting remarks. He observes, that when ophthalmy has reached its second stage, which may be known by circumstances already referred to in the preceding columns, it must be clear that the above indications are no longer valid, and the fulfilment of them would destroy the eye.

In the second stage, every thing which has a tendency to produce farther weakness of the eye must be avoided, or suppuration will be the consequence: *the first indication*, therefore, specified by Beer, *is to let the eye be cautiously exposed, according as its tendency will allow, to its wonted stimuli again.* 1. By letting fresh, dry, and, if possible, a warmish air have free access to the organ. 2. By exposing the eye to as much light (not of a reflected description) as can be borne, not only without difficulty but with pleasure. 3. By moderately exercising the organ, especially in the inspection of agreeable diversified objects; a plan which is of infinite service, when the eyeball itself has been affected.

The *second indication* proposed by Beer *in the second stage of ophthalmy in general, is to apply tonic remedies, particularly those of a volatile kind, to the eye, which are to be discontinued in the event of suppuration.* 1. Beer praises the application of well-warmed linen compresses, which, if necessary, may be sprinkled with camphor; or in urgent cases he uses little bags of aromatic herbs and camphor; a practice in which I am disposed to think surgeons here will have little or no confidence. 2. However, when the eye is too irritable to bear the application of bags of aromatic substances, Beer sanctions the employment of poultices made of bread-crumb and warm herbs, or the pulp of a roasted apple. But this experienced author is very particular in qualifying his approbation of moist applications with a caution, that they must never be allowed to become completely cold on the eye, whereby they would do more harm in a quarter of an hour, than any good which may have been attained in many hours by their previous use. Hence, Beer employs poultices only in cases of necessity. In this country, "when the extreme vascular congestion and excessive sensibility are reduced, and the inflammation tends to become chronic, the use of cold lotions, of a slightly tonic quality, is substituted with great advantage for ablutions of warm water. The sulphates of alum and zinc are the best."—(*Travers, Synopsis, &c. p.* 252.) The employment of astringents also agrees with the advice delivered by Richter and Scarpa. Here then we find a point on which Beer differs from the generality of writers; but nothing is clearer to me than that his alarm about the ill effect of cold upon the eye in the second stage of ophthalmy, is only the fruit of some theories which he entertains, and not of impartial experience. 3. When there are small ulcers or pustules on the eyeball itself, Beer assures us, that great benefit is derived from dropping between it and the eyelids a tepid solution of the lapis divinus, the composition of which is elsewhere described (see *Lachrymal Organs*), and bathing the eye with the same application, to which a little of the vinous tincture of opium is added. Should this remedy fail in checking the progress of the ulcers or pustules, Beer recommends the addition of acetate of lead. 4. And, says the same author, when no decided amendment is produced within twenty-four hours, the suppurating points must be touched once or twice a day, according to the urgency of the danger, with a camel-hair pencil, dipped either in a watery solution of opium, or the vinous tincture of opium. In the worst cases, he even directs Hoffman's balsam, naphtha, or the Peruvian balsam to be mixed with the latter application.

But Beer observes, that when these remedies have been too precipitately employed, and any granulations or excrescences form, the treatment must be less active, and then these new productions will frequently recede of themselves; but if they should not do so, they may be removed with burnt alum or caustic.—(*B.* 1, *p.* 252.)

The third rule laid down by Beer *in the treatment of the second stage of ophthalmy*, cautions the practitioner not to apply the caustic or the knife to any of the morbid changes, which either originate during the first stage, and continue in the second, or make their first appearance at the period of suppuration, as, for instance, opacities of the cornea, eversion of one or both eyelids, &c. However, as exceptions to this advice, Beer adverts to the treatment of new-growths under the circumstances above specified, and to that of ab-

cesses of the eyeball, where the matter is of an unhealthy quality and so copious as to make an opening advisable, which practice, however, as a general one, he condemns. The other morbid changes, already alluded to, the practitioner must endeavour to remove simply by proper treatment of the second stage.—(*Beer, b.* 1, *p.* 254.)

Beer's *fourth rule in the treatment of the second stage* of ophthalmy in general, and of idiopathic ophthalmy in particular, when the suppurative process is extending itself and threatening to impair the health, is, 1st. To allow the patient such food as is both easy of digestion, and of a very nutritious quality, and even a moderate quantity of wine and spirituous drinks, if he has been accustomed to them. 2dly. To direct the patient to keep his eye exposed the greater part of the day, in a fresh, dry, and (if possible) mild air, and take just exercise enough in various ways to produce a slight degree of fatigue. 3dly. When the eye itself is affected with suppuration, and the sight is either thereby much impaired or quite lost, and, of course, the patient very unhappy and depressed, Beer considers it higly beneficial to let his spirits be improved by society.

The *fifth rule* or *general indication in the second stage* laid down by Beer, refers to the necessity of supporting the constitution when the suppurative process is attended with a general febrile disturbance. For this purpose, he recommends, 1st. The exhibition of calamus aromaticus, naphtha, and camphor. 2dly. If they prove ineffectual alone, they are to be joined with other tonics, especially bark. 3dly. The warm bath, which, in consequence of the sympathy between the skin and eyes, is particularly efficacious. 4thly. Rubefacients applied not far from the eye.—(*B.* 1, *p.* 257.)

As an appendix to these general remarks, delivered by Beer, on the general treatment of ophthalmy in its first and second stages, I annex the sentiments of some other writers, as either confirming or rendering questionable some of his statements.

According to Scarpa, when bleeding and other evacuations have been practised, the next most useful measure is the application of a blister to the nape of the neck. He observes, that the skin here and behind the ears has a stronger sympathy with the eyes than any other part of the integuments. On the other hand, the late Mr. Ware preferred blistering the temples, and says, "When the leeches have fallen off, and the consequent hemorrhage has ceased, I would advise a blister of the size of half a crown to be applied on the temples, directly over the orifices made by the leeches; and I have found, that *the sooner the blister has followed the bleeding, the more efficacious both have proved.*" He adds, that when ophthalmy is very violent, and resists common methods, the most beneficial effects are sometimes produced by the application of a blister large enough to cover the whole head.—(*P.* 43, 44.)

With respect to blisters, another modern writer particularly objects to their being applied near the eye, or on the temples, "where they never fail to prove injurious." There is (says he) "but one exception to this as a general rule; for it would seem, that blisters applied to the external surface of the palpebræ, in cases of purulent ophthalmia, tend considerably to diminish the purulency and chemosis."—(*Vetch on Diseases of the Eye, p.* 17.)

In the second stage of acute ophthalmy, the vinous tincture of opium (the tinctura thebaica) has been very extensively used as a topical application. In common cases, two or three drops may be insinuated between the eyelids and globe of the eye twice a day; but in other instances, attended with more sensibility, once at first will be sufficient. The late Mr. Ware, who brought this application into great repute, found that introducing two or three drops of this medicine at the inner canthus, and letting them glide gradually over the eye by gently drawing down the lower eyelid, proved equally beneficial and less painful than letting them fall directly upon the eyeball. Immediately the application is made, it usually creates a copious flow of tears, a smarting, and a sense of heat in the eyes; which inconveniences, however, soon cease, and the eyes become clearer and feel decidedly improved. But notwithstanding every exaggeration, unbiassed surgeons are now fully convinced, that the vinous tincture of opium is a proper application only when the inflammatory action has been previously diminished by blood-letting, aperient medicines, and blisters, and when the action of the vessels has been weakened by the continuance of the disease. Nor is any doubt entertained, that the late Mr. Ware went much too far when he recommended the vinous tincture of opium as a most effectual application in every species and stage of the disorder, from the most mild and recent to the most obstinate and inveterate.—(*P.* 51.) Scarpa has seen the necessity of limiting the use of the remedy in question, and has expressly pointed out, that it is useful only when the violence of the pain and the aversion to light have abated. Indeed Mr. Ware himself, a little before sanctioning its employment in all cases, has acknowledged, that in certain instances, in which the complaint is generally recent, the eyes appear shining and glossy, and feel exquisite pain on exposure to the light, no relief at all is obtained.—(*P.* 48, 49.) Mr. Travers has remarked, that "there are inflammations, which assume a chronic character in their commencement, evidently depending on a state of atony, of very partial extent, void of pain, and scarcely possessing any sign of inflammation except the congestion of the vessels, or, if any, so feebly marked as to encourage us to disregard them in the treatment. In such cases a single stimulus will often restore the healthy action at once. The vinous tincture of opium has acquired a nostrum-like importance from its restorative operation in such cases; a virtue, I believe, not proper to it. A drop or two of the zinc, or the lunar caustic solution, or water impregnated with calomel, or a minute portion of the citrine ointment, or any other stimulant, would do as much."—(*Synopsis, &c. p.* 252.)

Whenever the patient can easily bear a moderate degree of light, Scarpa directs all coverings to be removed from the eyes, except a shade of green or black silk. A brighter light should be gradually admitted into the chamber every day, so that the eyes may become habituated as soon as possible to the open daylight; for, as Scarpa truly states, nothing has a greater tendency to prolong and increase the morbid irritability of the eyes, than keeping them unnecessarily long in a dark situation, or covered with compresses and bandages.

Dr. Vetch has such a dislike to the plan of covering the eye, that he never suffers a shade to be worn, conceiving that, in conjunctival inflammation, it always does a great deal of harm, by preventing a free exposure of the eye to a temperate atmosphere.—(*On Diseases of the Eye, p.* 17.)

Besides the common remedies for inflammation, there are some very powerful means which may be employed for the relief of particular states of ophthalmy with great effect. Thus, as the latter author has observed, by means of hyosciamus, belladonna, and stramonium (see *Belladonna*), the important structure of the iris may be secured from injury, at the same time that other measures are adopted for checking the inflammation. Such medicines may even be applied, as a mechanical force, for detaching any recent adhesion.—(*Op. cit. p.* 18.)

The uses of the argentum nitratum are also very extensive: "the slightest application of it in substance (says Dr. Vetch) can often remove the highest degree of morbid sensibility to light, and instantaneously restore quietude to the organ; it can prevent incipient changes and obviate advanced ones; and may also be used in solution as a valuable sedative."

The mention of so stimulating and active a substance as the nitrate of silver having a sedative effect may excite surprise; but the fact is unquestionable, and well illustrated in the treatment of several diseases.—(See *Cornea* and *Iris.*) As another modern writer correctly states, it is remarkable that even the weaker forms of medicated lotions irritate, and none more than such as contain opium. The relief afforded by anodyne fomentations in general is very various. "I have known them (says Mr. Travers) objected to as painful, and patients inquire if they might not substitute warm water for the aqueous solution of opium, and infusions of poppy and hemlock. The same observation applies especially to painful herpetic cutaneous affections, and acutely irritable ulcers. Upon these a solution of opium often acts as a stimulant and augments pain, while the lunar caustic solution as often assuages it." At the same time, Mr. Travers

admits, that exceptions occur, and that he has met with cases, "in which no other application than the aqueous solution of opium could be borne." He has also known the vapour of laudanum afford the most marked relief to the irritability to light accompanying strumous ophthalmy.—(*Synopsis of the Diseases of the Eye, p.* 251.)

According to Dr. Vetch, it is impossible in cases of conjunctival ophthalmia, to possess an application of greater efficacy than the undiluted liquor plumbi subacetatis, for altering the morbid and purulent state of that membrane: he also describes nicotiana, externally employed, as a narcotic and astringent, of singular service in lessening the pain and tumefaction.—(*P.* 19.) However, the discordance among the best writers about the effects of favourite local applications, would lead me to enjoin rather attention to the leading principles of the treatment, than confidence in the superior efficacy of any particular drug or composition. As also the local applications should vary in the different stages of purulent ophthalmy, no single one will always be right. If Beer had delivered no observations of greater importance than his condemnation of Bates's camphorated lotion, and his praise of other styptic stimulating applications, his remarks would be of little value; but as he has pointed out the different stages of purulent ophthalmia in a very correct manner, and adapted his remedies to these various states of the disease, his information comprehends scientific principles, and becomes peculiarly interesting. The same praise belongs also to Dr. Vetch's observations on purulent ophthalmy, who, in some points, both of the description of the complaint and its treatment, has surpassed Beer.

Of the different kinds of ophthalmy, Beer's classification is very comprehensive. According to the situations in which ophthalmic inflammation first originates, he proposes a general division of it into three forms, as suggested by some of the older writers: viz. *inflammation of the eyelids*, or *blepharophthalmitis; inflammation of the parts between the orbit and globe of the eye;* and, lastly, *inflammation of the eyeball itself*, or *ophthalmitis*. He observes, however, that these distinctions seem to assign a considerable extent to the original seat of the affection; for the expression *inflammation of the eyelids* can only denote a case in which the disorder begins at once in all the parts composing the eyelids. In the same way, inflammation *of the parts between the eyeball and orbit* appears to signify, that all those parts constitute the original sphere of the complaint; while *inflammation of the eyeball* seems to denote that the disorder has begun at once in all the textures of which this organ is composed. But, fortunately, as Beer remarks, the extent of the original seat of genuine idiopathic inflammation of the eye is seldom thus considerable: being mostly restricted to particular textures, from which it first spreads farther only when neglected or injudiciously treated. Hence, certain subdivisions of the complaint are necessary; and, accordingly, Beer subdivides *inflammation of the eyelids*, first, into the *erysipelatous*, or *blepharophthalmitis erysipelatosa*, which commences in the integuments of these parts. Secondly, into that which originates at the edges of the palpebræ, in the conjunctiva lining these parts and the Meibomian glands, and which Beer denominates *glandular inflammation of the eyelids*, or *blepharophthalmitis glandulosa;* a case described by writers under an infinite number of names, and often confounded with complaints of a totally different nature. Thirdly, when the effects of the inflammation are confined to a small portion of the eyelid, it constitutes the disease termed the *inflammatory stye*, or *hordeolum*, which Beer says is rarely a simple inflammation, but complicated with a scrofulous habit; a proposition which I think will not receive any credit in England. Fourthly, as there is one more form of inflammation of the eyelids, Beer gives it the name of the *erysipelatous swelling of the corner of the eye*, or *anchylops erysipelatosa*, which affects the skin of the inner canthus immediately over the lachrymal sac. The name here suggested expresses precisely the seat of the inflammation, and, as Beer thinks, will tend to prevent the case from being mistaken for inflammation of the lachrymal sac. *Inflammation of the parts in the orbit* comprehends, first, *inflammation of the lachrymal gland;* secondly, *inflammation of the lachrymal sac*, a disorder which begins in the lachrymal sac and nasal duct, and generally extends with great rapidity over all the excreting parts of the lachrymal organs; and, thirdly, *inflammation of the caruncula lachrymalis*, or the *encanthis inflammatoria*.

In the same way inflammations of the eyeball admit of a classification, which is of the highest practical importance, first, into the *erysipelatous inflammation of the sclerotic conjunctiva*, the *ophthalmitis erysipelatosa*, which denotes that form of the disorder which is at first entirely confined to the membrane connecting together the eyelids and eyeball. Secondly, into *inflammation of the outer textures of the eyeball*, the *ophthalmitis externa*, originating in the cornea and sclerotica. Thirdly, into *inflammation of the innermost textures of the eyeball*, the *ophthalmitis interna*, which has two forms highly necessary to be recollected in practice; for the inflammation may begin immediately in the retina, choroides, the membrane of vitreous humour, &c. and spread from these textures to all the rest of the eyeball, being named *true internal inflammation of the eyeball*, or *ophthalmitis interna vera*, and thus discriminated from another case, which is originally seated in the iris, the adjoining corpus ciliare, the lens and its capsule, and afterward extends from these parts to the more deeply-situated coats, and to the texture of the vitreous humour. This last form of internal inflammation of the eyeball is named, both by Schmidt and Beer, *iritis*. The classification then embraces a view of the different forms of ophthalmy, as modified by constitutional causes; as the effect of contagious and infectious diseases, measles, small-pox, &c.; and as a complication of certain cachexiæ, like gout, rheumatism, and scurvy.

Although I have thus given a brief delineation of Beer's classification of ophthalmic inflammations, it is not my design, in the subsequent columns, to enter into a full consideration of every particular case above enumerated: first, because the limits of this volume will not permit me to do so; and, secondly, because some of these cases have been already considered in other parts of the work.—(See *Lachrymal Organs.*)

Common Inflammation of the Eyelids. This form of disease is said by Beer to affect the upper much more frequently than the lower eyelid, because the former obviously has a larger surface exposed to injuries from without: nor does the complaint always spread to the latter. From the margin of the eyelid, a very red, tense, painful swelling ariæe, attended with heat, throbbing, and a great deal of tenderness when touched It gradually extends over the whole eyelid; but seems to be plainly bounded by the edge of the orbit. The motion of the eyelid is always more or less obstructed, and, at length, when the inflammation has reached its greatest degree, it is completely prevented. Nor is there any difficulty in comprehending why, when the inflammation has become severe, the eye should be excessively dry, and every attempt on the part of the patient to move the eyelid should be productive of considerable pain, and of a sensation as if some sharp extraneous substances lay under the lid; for, at this period, the palpebral conjunctiva is already severely inflamed, and, consequently, the secretion of mucus from the Meibomian glands is immediately stopped by the inflammation itself, while that of the tears is interrupted partly by the extension of the inflammation to the sclerotic conjunctiva, and partly by the effect of the sympathetic connexion existing between the conjunctiva of the eyelid and that of the eyeball. To this last cause, viz. sympathy, Beer refers the supervening dryness and shrivelling up of the lachrymal papillæ, as well as the apparent closure of the puncta lachrymalia, and the uneasy dry state of the edges of the eyelids. Hence, also, the dryness of the adjacent nostril, and a very disagreeable smell of dust, obliging the patient to sneeze repeatedly, which act is constantly attended with a great increase of pain in the swelling, a transient shooting of it to the eye and head, and a sensation as if flashes of light were elicited within the eyeball; a kind of hallucination, technically named *photopsia*. As the original seat of the inflammation is already extensive, one may readily understand, says Beer, why the affection in its first stage, particularly when neglected or badly treated, should frequently give rise to some febrile disturbance of the system.

In the second stage of the case, or that of suppura-

tion, which follows when the inflammation is violent and not soon dispersed, matter forms with the annexed train of symptoms. The redness suddenly increases very much, the eyelid becoming of a brownish-red, and lastly of a purplish-red colour. The swelling becomes more prominent, and presents a conical eminence, either in the middle of the eyelid or close to the outer or inner canthus. The pain is irregular, and of a stinging, burning kind, a throbbing being felt only in the deeper part of the tumour. At length the swelling becomes somewhat softer and less sensible at its most projecting point. The secretion from the Meibomian and lachrymal glands, which, in the first stage of the disorder, was suppressed, is now quite re-established, but more copiously than in the healthy state. During sleep, a quantity of mucus accumulates between the edges of the eyes, and glues them together. An extraordinary sensation of cold and heaviness is felt all about the eye. Ultimately, the most prominent point of the swelling presents a pale-red colour, followed by a yellowish livid tinge. As the abscess is now completely formed, the fluctuation of matter can be plainly felt.—(*Beer*, *b.* 1, *p.* 269, *&c.*)

According to the same author, nothing very particular is known respecting the causes of the preceding form of ophthalmic inflammation, and, with the exception of blows, he has not been able to discover the precise circumstances which give rise to it.

With regard to the prognosis, if the treatment be neglected or injudicious, the inflammation may suddenly become so violent as to produce in weak subjects gangrenous mischief. But when the case is properly managed in its first stage, the second, or that of suppuration, never ensues; yet, says Beer, the curative measures must be decisive, and no time wasted on trifling means, though due regard must be paid to the constitution. When the inflammation subsides favourably, no vestiges of it remain, and even the redness, which is the latest in disappearing, completely goes off in a few days, and the function of the eyelid becomes perfect again.

If gangrene and sloughing take place, the outer coverings of the eyelid are quite destroyed, and the consequences are an incurable eversion of the part (see *Ectropium*), or a hare-eye (see *Lagophthalmus*). When suppuration happens favourably, the abscess sometimes breaks very well of itself in the upper eyelid; but, according to Beer, this does not readily occur on the lower one, nor without the formation of sinuses, which sometimes run quite into the orbit. After the abscess has burst, or been opened, the part heals up with great celerity in favourable constitutions, but slowly in others; vermilion granulations arise from the bottom of the cavity, and a cicatrix follows which is scarcely perceptible. When the abscess is very large, however, and bursts of itself, the upper eyelid continues for some time very much weakened. If the collection of matter be neglected, or wrongly treated, or the subject be unhealthy, or the disease be aggravated by the effects of a damp atmosphere, hurtful food, severe mental trouble, wet poultices, or too long confinement of the matter, then, says Beer, fistulæ are apt to be produced, sometimes complicated with necrosis of the bone, the certain effects of which are some permanent and mostly incurable disease of the eyelid, and impairment of its functions: 1st. A closure of the lachrymal canals with a permanent stillicidium. 2. A complete obliteration of the same tubes, with an incurable stillicidium. 3. A prolapsus of the upper eyelid, from distention of the skin by the long confinement of the matter. 4. Inversion of the edge of the eyelid, from a shrinking of its cartilage. 5. Eversion of the eyelid, and hare-eye, from loss of skin.

As in this species of inflammation the organ of sight cannot well be affected, unless the disorder extend itself very much, the exclusion of air and light is here but of little use. Linen compresses well wet with very cold water, or vinegar and water, are to be applied; and, while the complaint is local, leeches are to be used; but if the constitution be threatened with febrile symptoms, then Beer urges the necessity of venesection, low diet, purgatives, and general antiphlogistic measures.—(*B.* 1, *p.* 275.)

In the second stage, with the exception of a few points, Beer states, that the case is to be treated like any other common abscess. When the matter is situated in the middle of the upper eyelid, not far beneath the skin, the abscess may be allowed to burst of itself, especially if the patient have a great dread of the knife. But if the matter lie near the outer or inner canthus, it should be let out with a lancet as soon as its fluctuation is quite distinct, the incision being made in the direction of the fibres of the orbicular muscle. When fistulæ or gangrene have already taken place, the treatment should be like that which is applicable to the same kind of mischief in most other parts of the skin.

Erysipelatous Inflammation of the Eyelids usually affects both these parts together, very seldom only the upper one, and never the lower alone. When also both are affected, the disorder always presents itself in the greatest degree in the upper eyelid. A pale, yellowish-red, seemingly transparent, shining swelling arises from the edges of the eyelids, and rapidly extends itself without any determinate boundary, the faint-red colour being gradually lost upon the eyebrow above, and not unfrequently upon the cheek below. When the inflamed part is gently touched, the redness disappears, but only for a moment. At length the swelling towards the margins of the eyelids becomes exceedingly soft, and feels like a vesicle that has been raised by a blistering plaster. The pain is inconsiderable, not attended with throbbing, but rather with a sense of heat and stiffness; when the part is slightly touched, the patient experiences a lancinating sensation in it. Its temperature is not much increased. The secretions from the Meibomian glands, lachrymal gland, and mucous membrane of the nostrils are much augmented. In a strong subject, the disorder, if genuine and idiopathic, is not productive of any constitutional disturbance; but in bad habits, and weak females and children, it is sometimes attended with fever. However, when the complaint partakes of the phlegmonous character, and is badly treated, the general symptoms are occasionally very severe at the change from the first to the second stage, and the case may then terminate in a gangrenous kind of suppuration. In irritable, delicate children, says Beer, when the disease spreads over the face, the case requires the most skilful treatment to prevent a disastrous termination.

In strong persons, the second stage of this disorder rarely ends in a manifest suppuration, but is rather in an exudation of lymph, which, becoming dry, forms small, delicate, branny scales, in the composition of which the desquamated cuticle has also a considerable share. In other instances, vesications of various sizes are formed on the erysipelatous surface, and burst, and discharge a fluid, which is converted into yellowish scabs.

According to Beer, the skin of the eyelids is particularly prone to erysipelatous inflammation. He considers the sudden effect of a cold blast of air, or of very cold water upon the skin of the eyelid, while in a state of free perspiration, as the most common cause of its being attacked with erysipelas, particularly in weak subjects. He states, however, that the complaint may be occasioned by the sting of bees, wasps, and other insects; accidents, which, when the stings are not extracted, are liable to be followed by a violent and dangerous general inflammation of the eyelid, not unfrequently extending in a perilous degree to the eyeball itself.—(*B.* 1, *p.* 281.)

With regard to the prognosis, no other case of ophthalmic inflammation so frequently subsides without the aid of surgery as this, provided the constitution be healthy and strong; and when the complaint is resolved in its first stage, the vestiges of it afterward are as little as those consequent to common inflammation of the eyelids.

The second stage, however well treated, is followed for a long time by a peculiar sensibility of the skin to the impression of cold damp air, and a strong propensity to relapses. If, when the cuticle peels off, a patient of weak constitution sit in a current of damp cold air, or try to wash away the scales and scabs with cold water, Beer states that an œdematous affection of the eyelid will be produced, which is often very obstinate, and apt to occasion a temporary inversion of the ciliæ (*Trichiasis*), or a similar state of the edge of the eyelid (*Entropium*). And he observes, that when from neglect or bad treatment an erysipelatous inflammation of the eyelid terminates in suppuration, the abscess is not like a common one, but the matter rapidly makes its way out through several openings in the already

partially disorganized skin, and, in general, this state is followed by ill-conditioned tedious ulcerations, whereby a good deal of skin is always destroyed. Under these circumstances, all those consequences may be produced, which have been described as liable to take place from the second or suppurative stage of common inflammation of the eyelid. Gangrene and sloughing may even occur, when erysipelas of the eyelids is brought on by the unremoved sting of an insect, and efficient treatment is delayed.

The treatment recommended by Beer in the first stage consists in the application of cold water; and he remarks, that exposure of the part for a time to a cool, moist, but in other respects pure, atmosphere will often suffice for the removal of the complaint. When, however, the disorder increases and assumes a phlegmonous character, the directions given for the treatment of common inflammation of the eyelids are to be followed.

In the second stage of erysipelas of the eyelids, Beer praises the good effects of a mild, dry air, of an equal temperature, and recommends covering the parts with a light bandage, under which are to be put well-warmed linen compresses, which, for weak persons, should be sprinkled with camphor; or he directs the eyelids to be covered with bags of aromatic herbs; generally a very favourite plan with Beer, whenever he objects to moist applications. In such individuals, he observes that the cure will be promoted by gentle diaphoretic medicines, with which, when the debility is very great, camphor should be joined. In this country, erysipelatous inflammation of the eyelids is treated according to the principles applicable to other cases of erysipelas, with cold applications, leeches, purgatives, antimonials, and, if necessary, venesection. Should an abscess form, the same treatment is proper as in the second stage of common inflammation of the eyelids.

Glandular Inflammation of the Eyelids is considered by Beer as the disease of which all the various cases of purulent ophthalmy are only modifications, which he describes under the names of *idiopathic catarrhal ophthalmy*; *idiopathic catarrhal-rheumatic ophthalmy*; and *blepharo blennorrhœa*, or *ophthalmo-blenorrhœa*. The two latter terms comprehend the purulent ophthalmy of infants, the Egyptian ophthalmy, the gonorrhœal ophthalmy, &c.

Glandular Inflammation of the Eyelids, Beer knew very well, was so far a defective term, that it seemed to imply merely an affection of the Meibomian and mucous glands of those parts, whereas he means to express by this name the kind of inflammation, of which all the cases, usually called in this country *purulent ophthalmies*, are varieties and modifications, and in which the conjunctiva is also particularly affected.

Acute suppurative Inflammation of the Conjunctiva, divisible into the mild and severe forms, as proposed by Mr. Travers, appears, perhaps, a better name.—(*Synopsis, &c. p.* 96, *&c.*) Dr. Veteh, who also prefers the general term *conjunctival inflammation*, observes, that from many internal and external causes, the membrane of the conjunctiva is liable to become the seat of inflammation, more especially that portion of it which gives a lining to the inner surface of the eyelids. The disease in its general nature, he says, differs little from that which is met with in other parts having a similar surface, as the nose, the fauces, the bronchial cells, and the urethra; but the continuation of the membrane forwards upon the anterior portion of the eye, and the consequent liability of the inflammation to affect this important organ, attach much interest to all the circumstances capable of producing it.—(*On Diseases of the Eye, p.* 148.) In the common glandular inflammation of the eyelids described by Beer, which seems to me to correspond to the more moderate forms of *purulent ophthalmy* met with in this country, either the whole, or only that part of their edges which is near one or both canthi, is affected with a very red, hardish, sensible swelling, attended with a violent annoying degree of itching. This swelling, Beer observes, does not extend far over the outside of the eyelid upwards or downwards, at most not more than a few lines; but it spreads over the palpebral conjunctiva, especially when neglected or badly treated, and the constitution is weak. This, he says, can only be discovered when the eyelid is everted. The farther the swelling extends over the inside of the eyelid, the more is the motion of the part obstructed; not on account of any want of power in the orbicular muscle, but from a fear of the pain with which every attempt to move the eyelid is accompanied. The itching which continually distresses the patient more or less, is often succeeded by an irritating burning kind of pain, which is particularly experienced when the eyelids are moved, and hence the patient is obliged, as it were, to keep his eye closed. While the inflammation is restricted to the edges and conjunctiva of the eyelids, and the Meibomian glands situated under it, though the secretion from these glands is entirely stopped, that from the lachrymal gland is much augmented, and consequently the disease is associated with a true *epiphora*, which is seriously aggravated whenever the eye is exposed to a strong light. As under these circumstances, the tears are not properly blended with the Meibomian secretion, they must of course be very irritating to the eye and its surrounding parts, and less fitted for properly lubricating its surface. Hence, the pain now becomes burning, and not unfrequently the cheek over which the tears run is excoriated. As soon as the inflammation of the eyelids spreads farther, and begins to affect the sclerotic conjunctiva, the effusion of tears ceases, the eye becomes preternaturally dry, and the patient constantly thinks that he feels sand under the eyelids, which sensation is rendered almost intolerable by any motion of the eye or eyelids. Children and women have so great a dread of this painful feel, that much persuasion is often requisite to induce them to let the eye be properly examined. If the glandular inflammation of the eyelids attain a considerable degree, the lachrymal papillæ shrink, and the puncta seem closed, which is particularly the case when the disorder begins at the inner canthus.

In the *second stage* of the complaint, Beer describes the itching, burning sensation, and dryness of the eye as undergoing a remarkable diminution, as either the canthi, or the whole extent of the edges of the eyelids become more and more moist and smeared with mucus, *an increased secretion of a puriform sebaceous fluid from the Meibomian glands being the first symptom denoting the commencement of the second stage of the inflammation.* As this mucous secretion is not mixed with an adequate quantity of tears, it inspissates in the form of white, thin, delicate layers, which from time to time cover the cornea, and make the patient very apprehensive of becoming blind, as the flame of a candle in the evening, and other objects, appear to him more or less concealed by a dense mist. When under these circumstances, however, the eyelids are repeatedly and briskly moved, or the eye is wiped, these appearances soon go off, the flakes of mucus being removed from the cornea. These accumulations of thickened mucus, Beer remarks, are apt to be most frequent and troublesome some time after a meal; and the eyelids become so firmly glued together during sleep with yellowish crusts, that when the patient awakes in the morning, it is not till after a great deal of washing and bathing of his eyes with warm water that he is able to open them again. The above-described change in the quantity and quality of the secreted matter as already mentioned, indicates the *first period of the second stage*; for Beer wishes it to be particularly noticed, that here, as in all inflammations of mucous membranes, the second stage of the disorder has three periods, to which the practitioner cannot be too attentive.

This morbid secretion of a mucous sebaceous matter does not continue long unattended with other effects; and very soon the peculiar appearances of suppuration are seen, at the same time that the conjunctiva of the eyelids becomes more considerably swelled, and a discharge takes place, not only from the canthi or margins of the eyelids, but from the whole of the thickened villous surface of the palpebral conjunctiva, and which discharge is distinguishable at first view from the mucus, which, at an earlier period, accumulated in much smaller quantity only between the edges of the eyelids and at the canthi. It is now no longer white, but yellow, completely like pus, with which it is in reality blended; and so viscid is it, that the crusts which collect on the eyelids in the night time, cannot be removed without pulling the eyelashes away with them. Sometimes, says Beer, at the moment of suppuration, minute pustules, which are scarcely distinguishable, form either at the canthi or along the edges of the eyelids, and are soon burst by the constant fric

sion of the parts. These pustules indicate the second or *suppurative period of the second stage* of the case, when either merely the canthus, or the whole of the margin of the eyelid constantly becomes excoriated, and secretes mucus and purulent matter, the sore fretted places smarting so severely on exposure to the air, particularly to such as contains a large proportion of carbonic acid gas and nitrogen, that the patient is afraid of opening his eye. When the patient neglects himself, and continues in an unhealthy atmosphere, these excoriations of the skin occurring in the suppurative stage are always more extensive; nay, they sometimes spread over the lower eyelid and down the cheek.

At length, after the excoriations have lasted, perhaps, several weeks, the suppurative process is checked and suppressed, either by surgical treatment, or accidental favourable circumstances, as change of regimen, weather, climate, &c., and then the excoriations immediately diminish. However, a morbid secretion from the Meibomian glands still continues, making *the third period of the second stage*, and is apt to become habitual, if not rectified by art, or removed by the effect of accidental favourable circumstances, when it changes into a thin serous discharge, and then terminates.

Beer refers the causes of *glandular inflammation of the eyelids*, or *simple purulent ophthalmy*, to the immediate operation of various stimuli acting chemically upon the edge of the eyelid, and upon the exposed follicles of the glands of the eyelid towards the inner canthus. Hence, says he, when many men are living together in a polluted, noxious air, impregnated with extraneous substances, this form of inflammation is found to occur even in the strongest constitutions with such frequency, that it seems as if it were epidemic. And, according to Beer, the principal cause of the disease will be found to be in the atmosphere, and the next most frequent occasion of it, he observes, is uncleanliness, as washing the eyes with foul water, &c. At the same time, he seems aware that this explanation would not of itself be always quite satisfactory; for he adds, that although under the above circumstances no constitution, no sex, nor age is spared, there must be some particular condition which is conducive to the disorder, or at all events to its more rapid and severe course, and the quick extension of the inflammation in certain individuals, which condition, he supposes, must depend either upon weakness of constitution, or upon excessive irritability, or, as he terms it, *vulnerability* of the whole surface of the body. Beer makes no mention of the effect of damp nocturnal air in warm countries as giving origin to purulent ophthalmy, so much insisted upon by Asalini and Dr. Vetch; but which doctrine, in reference to the origin of purulent ophthalmies in England, I think, completely fails; and what is still more worthy of notice, Beer never attempts to explain the propagation of the disease by its infectious nature. It is observed by Dr. Vetch, that the history of all diseases originating from some particular impression received from the atmosphere, but capable when formed of propagating themselves by contagion, is rendered particularly difficult; because the same circumstances, which favour the communication by contagion, produce also a predisposition to be acted upon by the more general causes existing in the atmosphere. The principal cause which gives force and opportunity to the action of contagion, is the crowding individuals together into too limited spaces. The same circumstance Dr. Vetch has seen give a predisposition to diseases of an epidemic, but not a contagious nature; and hence he infers, that it may produce the same predisposition to diseases, which are both contagious and atmospheric.—"The appearance of ophthalmia among the crews of ships and in barracks was often met with long before the late destructive and virulent disease (presently to be described). In the army, such an ophthalmia has extended to whole regiments, without any appearance of the disease among the inhabitants of the neighbourhood; and while the free intercourse which subsists among the men, as to washing in the same water, using the same towels, and sleeping more than one in a bed, readily accounts for the rapid extension of the disease in the same corps, yet the excessive crowding together of men will often of itself engender inflammation of the conjunctiva."—(*On Diseases of the Eyes*, p. 171.) I believe, with respect to the causes of all purulent ophthalmies, our present knowledge will permit us to venture no farther than the tenor of the preceding observations, which is, that they originate epidemically, but probably multiply both in this manner, and by the infectious matter of the disease being inadvertently applied in various ways to the eyelids of other persons. This species of inflammation of the eyelids is rarely met with by the surgeon in its first stage, because only very timorous patients then seek medical advice; and most individuals, who feel in other respects well, relieve themselves by washing the eyes with cold water, and applying cold poultices, made of bread-crumb softened in water. Besides, when the disease is not very severe, it frequently subsides of itself; as in a favourable constitution, a better air is sometimes capable of restoring the healthy state of the eye. If, however, the disease at its commencement should be violent, or attack an individual of very weak habit, Beer states that it may immediately affect not only the Meibomian glands, but the perichondrium of the cartilage of the eyelid, and produce an incurable entropium, which is also sure of taking place when the case is neglected, and followed by deeply extending ulcerative mischief. When the complaint is strictly idiopathic, it never brings on any general indisposition, except, by improper treatment, it should happen to be converted into a violent inflammation of the whole eyelid, which, according to Beer, only happens in weak subjects, and women and children, whose skin is in a very irritable state, or when a person of apparently good constitution remains under the influence of circumstances which tend to augment the inflammation as, for instance, exposed to the air of a stable, privy, &c., in which event, Beer describes the inflammation of the eyelids as being quite of a peculiar description.

As for the prognosis in the second stage, Beer observes, that if the excoriations at the suppurative period should spread all over the edges of the eyelids, and compel the patient to keep his eye incessantly shut, a partial adhesion of the eyelids to each other (*anchyloblepharon*) may be the result. Also, when, at either of the periods of the secretion of mucus, or at that of suppuration, the patient is content with merely softening with warm water the thick matter glueing the eyelids together, so as just to be able to open his eye, and does not completely free the eyelashes from the crusts, clusters of hairs will project inwards (see *Trichiasis*), whereby a secondary inflammation of the conjunctiva of the eyeball will be excited, which, Beer says, should be carefully discriminated from a mere extension of the glandular inflammation of the eyelid. Such a trichiasis, he observes, may easily become incurable, when the edge of the eyelid is seriously injured by the depth of the excoriations. But if the suppurative process be restricted chiefly to the canthus, especially the outer one (which case, according to Beer, is not unfrequent in old, debilitated subjects of a relaxed constitution), and if the excoriations should deeply penetrate the commissure of the eyelids, this may be completely destroyed, and the lower eyelid everted.

As the state of the atmosphere, uncleanliness, crowded and close places, &c. are considered by Beer to be the principal causes of the glandular inflammation of the eyelids, or simple purulent ophthalmy, one of the most important indications in the first stage of the disorder, seems to him to be the removal of these hurtful circumstances. And he declares, that if immediate attention be not paid to such indication, it will be quite impossible to prevent a dangerous increase of the disorder. A cool fresh air, and bathing the eye with cold water, or a weak lotion of vinegar and water, Beer represents to be means usually adequate to stifle this inflammation in its birth. In the second stage, he says, the indication is entirely different.

But also in the beginning of this stage, and even at its second period, namely, that of suppuration, taking place, the disorder, according to Beer, seems for a short time to be benefited by the employment of cold water; but the consequences are rendered by such treatment a great deal worse; for a fresh much more extensive inflammation of the same kind again takes place. At the first period of the second stage, viz. while the secretion is a pure mucous and sebaceous matter, Beer says, that it is absolutely necessary to employ such external means, as are calculated to promote the action of the veins and absorbents. For this purpose he recommends the following collyrium: ℞. Aq. rosæ ℥iv. Hydrarg. oxymur. gr. j. vel gr. dimidium. Mucil. sem

cydon. ℈j. Tinct. opii vinos. ℥j. Misce. This eye-water is to be used lukewarm from four to six times a day, and the eye afterward carefully and completely dried. No eye in this state, he says, will bear more than the proportion of one grain of the oxymuriate of quicksilver, and only seldom more than half a grain.

But as soon as the suppurative period commences, attended with excoriations, gentle astringents, like the liquor plumbi subacetatis, in a solution of the lapis divinus (see *Lachrymal Organs*), should be added to the above lotion, for which they may at length be entirely substituted. And when the suppurative period has terminated, but a morbid secretion of mucus yet obstinately continues, and threatens to become habitual, recourse should be had without the least delay to one of the following eye-salves, a bit of which, about the size of a small pea, Beer directs to be smeared once a day over the edges of the eyelids. ℞. Butyr. recentis insulsi ʒ ss. Hydrargyri nitrico-oxydi gr. x. Tutiæ ptt. gr. vj. Misce. This ointment, he says, will sometimes answer; but, that it is mostly necessary to use Janin's salve, composed as follows: ℞. Butyri recentis insulsi ʒ ss. Hydrargyri præcipitati albi gr. xv. Boli albi ℈j. Misce.

According to Mr. Travers, the mild acute suppurative inflammation of the conjunctiva is not attended with that excessive swelling of the eyelids, that intense pain, nor that profuse secretion, with which the vehement acute form of the disease is characterized. In the treatment, he directs a solution of alum to be early substituted for emollient fomentations, which he recommends to be freely used during the acute period. Simple purging and abstinence, he says, are generally sufficient to allay the febrile irritation, which is moderate. Topical bleedings, and blisters, kept open on the back of the neck, are also stated to be of great efficacy. "When the pain and irritability to light subside, and the discharge becomes gleety, the conjunctiva pale and flaccid, tonics, especially the extract of bark and the acids, do great good."—(*Synopsis, &c. p.* 264.)

Catarrhal ophthalmy, so called by Beer, is described by him as a species of glandular inflammation of the eyelids, attended with a simultaneous affection of the mucous membrane of the nose, trachea, &c., brought on by particular states of the weather, and attacking so many persons at once, as to appear epidemic. The prognosis and indications are the same as those in common glandular inflammation of the eyelids; with this exception, that attention must be paid to the affection of other organs, and both at the first and second periods of the second stage, such remedies given as operate powerfully on the mucous membranes and skin, and, in general, during the second stage, an equal, warm temperature, and gentle diaphoretics, with camphor, are highly beneficial.

Severe Purulent Ophthalmy.—The *Blepharo-blennorrhœa* and *Ophthalmo-blennorrhœa*, of Schmidt and Beer; including the *ophthalmia neonatorum*, the *Egyptian ophthalmy*, the *gonorrhœal ophthalmy*, &c.; on which varieties, however, I shall annex to this account some further particulars, as they relate to each of these cases individually; because, though the following history contains an excellent general description of the severe forms of suppurative inflammation of the conjunctiva, it leaves unexplained some of the circumstances on which its varieties depend.

The vehement acute suppurative inflammation of the conjunctiva is described by Mr. Travers as being sudden in its attack; a feature in which it particularly differs from the milder cases, usually met with in schools.—(See *Lloyd on Scrofula, p.* 321.) It is accompanied with most severe darting pains; and the upper eyelid is sometimes in a few hours prolonged upon the cheek, owing to the infiltration and enormous swelling of the tissue, connecting the conjunctiva to the tarsus. —(*Travers, Synopsis, &c. p.* 265.)

According to Beer, the modification of glandular inflammation of the eyelids, here to be considered, consists entirely in the rapid extension of the inflammation and suppuration, the disorder affecting, ere it is suspected, not only the whole of the conjunctiva of the eyelid, but also that of the eyeball, and the sclerotica and cornea. The swelling of the palpebral conjunctiva is described by Beer as being unusually great; at first soft, somewhat elastic, smooth, and readily bleeding; but afterward, in the second stage, hard and granulated, or, as another writer says, it "becomes preternaturally vascular thickened, and scabrous, or forms fleshy eminences."—(*Travers, Synopsis, &c. p.* 26.) The first stage is rapidly over. At the first period of the second stage, the secretion both of mucus and pus is surprisingly copious. First, the mucus is whitish and thin; but as soon as the suppurative process begins, it becomes yellowish and thick, and when an attempt is made to open the eyelids, it gushes out with such force, and in so large a quantity, as frequently to cover in an instant the whole cheek. Sometimes this mixture of mucus and matter contains light-coloured streaks of blood; but in worse cases, these streaks are dark and brownish, or else a thin ichor is discharged, in which case the progress of the disease is so rapid, that the eye can seldom be saved. The swelling of the conjunctiva of the eyelids, especially of that of the upper one, always increases during the first period of suppuration, and, when the discharge is more ichorous, the membrane is more granulated, so that, if the eyelid be opened carelessly, or during the child's crying, fits of pain, &c., the whole tumefied conjunctiva of the upper eyelid is immediately thrown outward, in the form of ectropium, and it is sometimes difficult, and even impracticable, to turn the part inward again, especially when the conjunctiva is already changed into a hard sarcomatous substance. While the swelling at the inner surface of the eyelids continues to increase, their outer surface, particularly that of the upper one, becomes reddened; but the redness is dark-coloured, inclining to brown, and when the child cries to blue. In children, the whole cheek on the affected side is very often swelled, and sometimes the mucous membrane of the lachrymal sac, and even of the nose, participates in the effects of the disorder. Sometimes at first, only one eye is affected, and the other is afterward attacked. And, according to Beer, just before the period of suppuration, it is by no means uncommon for rather a profuse bleeding to take place from the eye; an event which, though it seriously alarm the parents of the child, or an adult patient, is hailed by the experienced surgeon as a favourable omen; for in such cases, the suppuration is generally very mild, and not of a destructive kind, and the swelling of the conjunctiva of the eyelids, as well as that of the sclerotic conjunctiva, if already present, soon undergoes a remarkable diminution after such hemorrhage, which often occurs two or three times. When, during the first very short and transient stage, the inflammation extends also to the sclerotic conjunctiva, this membrane forms a pale-red, soft, irregular swelling, all round the cornea, which at length seems so buried, that, at the period of the mucous secretion, its centre can hardly be discerned; and, when suppuration begins, both mucus and pus are discharged from the conjunctiva of the eyeball in profuse quantity, particularly accumulating over the cornea, and not unfrequently drying into a thick pellicle, when long detained in the eye. Hence, the case looks as if the whole eyeball, or, at least, all the cornea, were in a state of complete suppuration. At length, the tumefied conjunctiva of the eyeball becomes sarcomatous, though never in such a degree as that of the eyelids. When the suppurative period ceases, and with it the most urgent danger to the eye, the secretion of mucus alone continues, as at the first period of the second stage; the swelling of the conjunctiva of the eyelids, and of the sclerotic conjunctiva when this has also been affected, diminishes; and the disorder ends in an increased effusion of tears, or true epiphora. When the effects of the suppuration upon the conjunctiva of the eyeball are more severe, the corneal production of this membrane in the most favourable cases is raised from the subjacent cornea, and so opaque, that the eyesight is lost, or at all events seriously impaired, until the transparency returns, which is sometimes late, especially when efficient treatment is not put in practice. Should the suppuration be very deep, the cornea, which always turns whiter and whiter, presents near the edge of the swelling of the conjunctiva an arrangement similar to that of the leaves of an old book, and at length seems converted into a mass of purulent matter, which projects more and more out of the depression in the swelled conjunctiva, and then bursts in its centre either quickly and with very violent pain, or slowly without any suffering, an oval hole being left, behind which the yet transparent crystalline lens appears, included in its undamaged capsule. At this period, adults can often see very plainly, and fancy their recovery near at hand, or, at least, all danger over. Already, however, every

part of the cornea has been more or less perforated by ulceration, the iris protrudes through all these apertures so as to form what has sometimes been named the staphyloma racemosum. In a very short time, not exceeding a few hours, the capsule of the lens is affected and burns like the cornea, when it is discharged, either with or without a portion of the vitreous humour. At length, the suppuration subsides, and with it the protrusions of the iris, the opening in the cornea becoming closed with a brown or bluish opaque flat cicatrix. But if in this destructive form of suppuration, nothing is done for the relief of the disease, the whole eyeball suppurates, the eyelids become concave instead of convex, and the fissure between them closes for ever. In adults of feeble constitution, when the case is not properly treated, but particularly in weak children, this excessively violent form of conjunctival inflammation and suppuration spreads with such rapidity, that a considerable general disturbance of the system is occasioned. Indeed, according to Mr. Travers, in the common course of this vehement form of conjunctival suppurative ophthalmy, the system sympathizes; chilliness is succeeded by a hot and dry skin; and the pulse is frequent and hard. Yet it is particularly pointed out by the army surgeons, that one peculiarity of the Egyptian purulent ophthalmy is its being generally attended with little constitutional disturbance. When the above-described annihilation of the eyeball takes place, it always creates violent general indisposition in unhealthy, weak children, and even leaves adults for a long while afterward in an impaired state of health.

According to Beer, who appears to have no idea of infection being concerned, the particular cause of this unfortunate extension of idiopathic glandular inflammation of the eyelids, both in infants and adults, frequently depends altogether upon the foul atmosphere in which they are residing, and hence, says he, the disorder is, as it were, endemic in lying-in and foundling hospitals, where the air is much contaminated by effluvia from the lochia, the crowding together of many uncleanly persons, dirty clouts, &c. The unjustifiable folly of exposing the eyes of new-born infants to every degree of light; a tedious labour, in which the child's head is detained a long while in the vagina, and roughly washing the eyes after birth with a coarse sponge, are other circumstances supposed by Beer to be conducive to the origin of the complaint in new-born infants. The reality of many of these causes I regard myself with a great deal of doubt; and as for his conjecture, that sprinkling cold water on the head in baptism, while in a state of perspiration, may produce the complaint, it is too absurd to need any serious refutation. The disorder, he says, is always more rapid and perilous in new-born infants than adults (*B.* 1. *p.* 318); a remark which does not agree with the statements usually made, if the Egyptian ophthalmy, as seen in the army, be comprehended. It is observed by Mr. Travers, that the highly contagious nature of the suppurative ophthalmia, whether in the mild or vehement acute form, is sufficiently proved. For one person, affected with this disease, above three months old, he thinks at least twenty are attacked under that age. "The mother is the subject of fluor albus, or gonorrhœa, and the discharge is usually perceived about the third day."—(*Synopsis, &c. p.* 97.) Some farther observations on the causes of some of these severe modifications of glandular inflammation of the eyelids will be introduced, after the prognosis and treatment have been considered. This will be the more necessary, as the propagation of the disorder by infection is here entirely overlooked.

According to Beer, whenever an idiopathic inflammation of the glands of the eyelids attains the severe forms exhibited in the purulent ophthalmy of infants, the Egyptian ophthalmy, and gonorrhœal ophthalmy, the prognosis must naturally be unfavourable, and this in a greater degree, the more the inflammation and suppuration have extended to the eyeball itself. The cases are still more unpromising, when they happen in poor, half-starved, distressed individuals whom it is impossible completely to extricate from the circumstances which either cause, or have a pernicious effect upon, the disease. Should an incidental ectropium not be immediately rectified, says Beer, it will continue until the end of the second stage, and even frequently longer, so as to require particular treatment. When at the period of suppuration, merely the layer of the conjunctiva spread over the cornea is destroyed, the prognosis, in respect to the complete recovery of the eyesight, is favourable, although it takes place but slowly. If the effects of the disease at this period should be deeper, yet the cornea not destroyed, only rendered flat and somewhat opaque; or if the cornea should be ulcerated at a very limited point, there will remain, in the first case, an opacity of the cornea; but in the second, a partial adhesion of the iris to the latter membrane (synechia anterior) is apt to follow, with a more or less extensive cicatrix on the cornea, covering in a greater or less degree the lessened and displaced pupil, and thus diminishing or preventing vision. When, during the inflammation and suppuration, a considerable part or the whole of the iris adheres to the cornea, and this is not penetrated by ulceration, the result, in the first case, is a *partial*, in the second, a *complete staphyloma* of the cornea, which does not fully develope itself until towards the decline of the second stage of the ophthalmo-blennorrhœa. If the inflammation should spread to the textures of the eyeball itself, so as to produce severe constitutional disturbance, the eye wastes away in the midst of the profuse discharge, the eyelids sink inwards, and the fissure between them becomes permanently closed.—(*Beer, b.* 1, *p.* 319.)

Beer notices the opinion of the celebrated Schmidt, which was, that the ophthalmo-blennorrhœa, or purulent ophthalmy involving the sclerotic conjunctiva, always has a fixed duration of a month, in new-born infants, and of six, eight, or twelve weeks in debilitated individuals. Beer acknowledges the correctness of this opinion, only in cases where the surgeon has to deal with a completely formed ophthalmo-blennorrhœa, and not in a more recent case, or one in which the disease is chiefly confined to the inside of the eyelids.—(*Blepharo-blennorrhœa.*) When the disorder is met with in the first period of the second stage, or it is confined to the palpebral conjunctiva and Meibomian glands, and truly idiopathic, Beer asserts that its course may be restricted by efficient treatment to a few days, as he has often proved in the establishment for foundlings at Vienna.

It is farther remarked by Beer, that in this modification of genuine idiopathic glandular inflammation of the eyelids, the indications have something peculiar in them. If, by chance, the surgeon meet with the disease in its first stage, it will be most benefited by the application of folded linen wet with cold water; and sometimes a brisk purge of jalap and calomel, and putting a leech over the lachrymal sac at the inner canthus, will promote the subsidence of this dangerous species of ophthalmy. The case, however, rarely presents itself for medical treatment thus early, and *in hospitals*, Beer says, *antiphlogistic treatment is, on this account, hardly ever indicated.*

With some exceptions of importance, the treatment advised by Beer, for the second stage of these severer forms of purulent ophthalmy, resembles that proposed by him for the second stage of simple glandular inflammation of the eyelids, or the milder varieties. These more severe kinds of purulent inflammation of the eye, implied by blepharo-blennorrhœa and ophthalmo-blennorrhœa, he says, should never be viewed and treated merely as local disorders; but that, both in children and adults, internal remedies should be exhibited, particularly volatile tonic medicines. In cases where the cornea is already attacked by a destructive ulcerative process, manifold experience has convinced him that bark, combined with naphtha, and the tincture of opium, is the only means of saving the eye; but that, if the suppuration be confined to the eyelids, the decoction of calamus aromaticus with naphtha and opium will mostly answer. When, on the supervention of suppuration, the pain in the eye and neighbouring parts is excessively severe, Beer assures us, that friction with a liniment of opium will give great relief. In new-born infants, the maternal milk of right quality will mostly do more good than internal medicines: but if the case be urgent, and the child feeble, Beer thinks volatile medicines may sometimes be useful.

With respect to particularities, made necessary in the local treatment by the modified nature of the inflammation, Beer offers the following information: first, in new-born infants, or very young children, the oxymuriate of mercury cannot be used without danger, though blunted with mucilage; and even in adults it should be employed in these cases with great circum-

spection. Secondly, the mucus and purulent matter should not be allowed to remain long under the eyelids, as such lodgement is found to promote the destruction of the layer of the conjunctiva situated on the cornea; but at the same time, Beer thinks, that leaving any water on the eyes, after cleaning them, and letting it become cold there, will have quite as pernicious an effect. Hence, he is very particular in directing all the mucus and purulent matter to be wiped away from the eye with a bit of fine sponge, moistened with a warm mucilaginous collyrium, but not so wet as to let the fluid drop out of it; or when they are very copious and in large flakes, he even recommends them to be washed away by means of Anel's syringe; but he says that every part about the eye should be immediately afterward well dried with a warm napkin, and then covered with a warm camphorated compress. Thirdly, during the suppurative period, according to Beer, common tincture of opium, or the vinous tincture, is the best local application, the parts being smeared with it twice a day, by means of a fine camel-hair brush. It is only in a few instances, that a small proportion of the lapis divinus (see *Lachrymal Organs*), mixed with the mucilaginous collyrium, can be endured. Beer declares, that he has never seen any good produced by Bates's camphorated lotion, which was so highly praised by the late Mr. Ware. Fourthly, when the suppurative period has terminated, the mucous secretion again becomes white and thin, as at the very commencement of the second stage, but it is always more copious; now is the time (as in the last stage of simple glandular inflammation of the eyelids) when the topical use of mercury, joined with styptics, especially in the form of an eye-salve, is indicated. Fifthly, if an eversion of the upper eyelid should happen from washing the eye carelessly, or the mere crying of the infant, in consequence of the thickened granulated state of the palpebral conjunctiva, the position of the eyelid must, if possible, be immediately rectified; for afterward this cannot be done. In order to avoid this ectropium, the eyelids should never be opened while the child is crying, or in any way agitated; for at such periods, the thickened scabrous conjunctiva will suddenly protrude, and cannot be kept back. Beer says, that the eyelid should be replaced in the manner directed by Schmidt.—(*Ophthal. Bibl.* 3, *b.* 2, *Stück*, *p.* 149.) The surgeon, having smeared the ends of the thumb and fore-finger of each of his hands with fresh butter, is to take hold of the everted cartilage of the eyelid at the outer and inner canthus, draw it slowly a little upwards, and then suddenly downwards. Thus the thickened conjunctiva, if not too fleshy and granulated, may be quickly reduced, and the ectropium removed. But if the swelling of this membrane should be already very considerable, and have begun to be hard and studded with excrescences, the thumbs should be placed so as to compress rather the middle of the eyelid. However, if the ectropium cannot be at once removed, it is to be treated, after the termination of the second stage of the purulent ophthalmy, as a sequel of this disorder. —(See *Ectropium*.)

In the ophthalmo-blennorrhœa, the alteration of the sclerotic conjunctiva is said by Beer to be very different from chemosis; a remark which is strictly correct, inasmuch as ordinary chemosis is not attended with that change in the surface of the sclerotic conjunctiva, which fits it for the secretion of pus. But if we are to understand by chemosis a copious effusion of lymph in the loose cellular substance between the conjunctiva and the eyeball, this state must be admitted as one of the usual effects of severe purulent ophthalmy.

"It is after this morbid condition, which is characteristic of the suppurative ophthalmia (says Mr. Travers), that the conjunctiva forms fungous excrescences, pendulous flaps, or hard callous rolls protruding between the palpebræ and globe, and everting the former, or, if not protruding, causing the turning of the lid over against the globe. The tarsal portion takes on from the same cause the hard granulated surface, which keeps up incessant irritation of the sclerotic conjunctiva, and at length renders the cornea opaque."—(*Synopsis*, *&c. p.* 98.)

The treatment recommended by Mr. Travers for the vehement acute suppurative inflammation of the conjunctiva, consists in a very copious venesection, by which, he says, the pain is mitigated, if not removed; the pulse softened; and the patient sinks into a sound sleep, and perspires freely. The high scarlet hue and bulk of the chemosis are sensibly reduced, and the cornea is brighter. The blood-letting, if necessary, is to be repeated, and the patient briskly purged, every dose of the opening medicine being followed by a tea-spoonful of a solution of emetic tartar, so as to keep up a state of nausea, perspiration, and faintness. When the discharge becomes thin, gleety, and more abundant, the swelling of the eyelid subsides, the conjunctiva sinks and becomes pale and flabby, the pain and febrile irritation are past, and the cornea retains its tone and brightness, Mr. Travers considers the case safe, and states that the prompt exhibition of tonics, with the use of cooling astringent lotions, will prevent its lapsing into a chronic form. "But if, when the lowering practice has been pushed to the extent of arresting acute inflammation, the patient being at the same time sunk and exhausted, the cornea shows a lack lustre and raggedness of its whole surface, as if shrunk by immersion in an acid, or a gray patch in the centre, or a line encircling or half-encircling its base, assuming a similar appearance, the portion so marked out will infallibly be detached by a rapid slough, unless by a successful rally of the patient's powers, we can set up the adhesive inflammation, so as to preserve *in situ* that which may remain transparent."—(*Synopsis*, *&c. p.* 266.) Here we find some approximation of practice between Mr. Travers and Professor Beer; but it is almost the only point in which any resemblance can be found in their modes of treatment.

The granulated or fungous state of the palpebral conjunctiva, produced by purulent ophthalmy, sometimes demands particular treatment after the original disease is subdued. If such state of the eyelid be not rectified, it often keeps up a "gleety discharge, irritability to light, drooping of the upper lid, a pricking sensation as of sand in the eye, and a preternaturally irritable and vascular state of the sclerotic conjunctiva; with these are frequently combined opacities of the cornea."—(*Travers*, *op. cit. p.* 271.) The affection, as conjoined with opaque cornea, is particularly noticed by Dr. Vetch, who describes the disease of the palpebræ as consisting, at first, in a highly villous state of their membranous lining, which, if not treated by appropriate remedies, gives birth to granulations, which in process of time become more deeply sulcated, hard, or warty. Along with the villous and fleshy appearance of the lining of the eyelids, there is a general oozing of purulent matter, which may at any time be squeezed out by pressing the finger on the part. The diseased structure is highly vascular, and bleeds most profusely when cut. It possesses, as all granulated substances do, a very great power of growth, or reproduction. Dr. Vetch has seen many cases in which it has been removed with more zeal than discretion, twenty or thirty times successively, without this disposition to reproduction having suffered any diminution. Indeed, he assures us that the operation was very unfavourable to the ultimate recovery of the part; "a new surface is produced of a bright velvety appearance, much less susceptible of cure than the original disease, and which, even if at length healed, does not assume the natural appearance of the part, but that of a cicatrized surface," not attended with a return of the transparency of the cornea. It is satisfactorily proved by the observations of Dr. Vetch, that this diseased state of the inner surface of the eyelid was not only known to Rhases and other old practitioners, under the names of sycosis, trachoma, scabies palpebrarum, &c., but that its treatment by the actual cautery, excision, and friction was also recommended by them. The honour of having introduced the preferable mode of cure with escharotics, Dr. Vetch assigns to St. Ives. No substances appear to Dr. Vetch more effectual for this purpose than the sulphate of copper and nitrate of silver. He says that they should be pointed in the form of a pencil, and fixed in a port-crayon. "They are to be applied, not as some have conceived, with the view of producing a slough over the whole surface, but with great delicacy, and in so many points only as will produce a gradual change in the condition and disposition of the part." As long as any purulency remains, Dr. Vetch states that the above applications will be much aided by the daily use of the liquor plumbi subacetatis When the disease resists these remedies, and the surface is hard and warty, he applies very minute quantities of finely-levigated powder of verdigris, or burnt

alum, to the everted surface with a fine camel's-hair pencil, but carefully washes them off with a syringe before the eyelid is returned. The caustic potassa, lightly applied to the more prominent parts of the diseased surface, will also answer.—(See *Vetch on Diseases of the Eye*, p. 73, *&c.*) Mr. Lloyd also gives his testimony in favour of the superiority of the nitrate of silver, which he has employed in the form of a saturated solution for restoring the healthy state of the inner surface of the eyelid.—(*On Scrofula*, p. 328.) The practice of excision was followed by the ancients, and revived of late years in England by Mr. Saunders, who did with scissors what Sir W. Adams and others have subsequently performed with a knife or lancet. Mr. Travers, I may observe, is also one of the advocates for the excision of the granulations and hardened excrescences of the conjunctiva. If there be a nebula of the cornea, with a plexus of vessels extending to it, these are then divided near the edge of the cornea, in the manner recommended by Scarpa. Mr. Travers afterward applies a solution of the sulphate of copper, the liquor plumbi subacetatis, or the vinous tincture of opium. One remark which he makes tends very much to confirm the general advantage of the practice inculcated by Dr. Vetch; for, it is observed, "the application of the blue-stone, or of the lunar caustic, is often useful in preventing the regeneration of the granulations after their excision."—(*Synopsis, &c* p. 272.) My friend Mr. Lawrence, whose experience in diseases of the eye is very considerable, informs me that he finds caustic the sure mode of permanently removing the granulated fungous state of the inner surface of the eyelid, and that, when the granulations are cut away, they are frequently reproduced; a fact on which Dr. Vetch has particularly insisted.

Egyptian Ophthalmy. One of the best accounts of this disease, as it appeared in the army, is that delivered by Dr. Vetch. Although there can be no doubt that the disorder, in all its general characters, closely corresponds to the severe form of acute suppurative inflammation of the conjunctiva, as described by Beer, yet it has some peculiarities. Thus, one thing noticed in the Egyptian ophthalmy, but not in other purulent ophthalmies, is, that *the first appearance of inflammation was observable in the* lining of *the lower eyelid.*—(*Peach, in Edin. Med. and Surgical Journ. for January*, 1807; *Vetch, on Diseases of the Eye*, p. 196.) According to the latter writer, the feeling of dirt or sand rolling in the eye, is a symptom requiring particular attention, as its accession is a certain index of the disease being on the increase. It is subject to exacerbations and remissions, the attacks always taking place in the evening, or very early in the morning. *The first stage of the disease* is said by Dr. Vetch to be *characterized by its great and uniform redness, without that pain, tension, or intolerance of light, which accompanies most other forms of ocular inflammation;* and, in particular, that in which the sclerotic coat is affected. From the very beginning of the complaint, there is a disposition to puffiness in the cellular texture between the conjunctiva and the globe of the eye, often suddenly swelling out into a state of complete chemosis, and at other times making a more gradual approach to the cornea. While effusion is thus taking place upon the eye, œdema is likewise going on beneath the integuments of the eyelids. This enormous tumefaction of the eyelids is said to be generally consentaneous with the complete formation of chemosis; entropium is produced, and the integuments of the two eyelids meet, leaving a deep sulcus between them. When the external swelling begins, the discharge, which was previously moderate, and consisted of pus floating in a watery fluid, changes into a continued stream of yellow matter, which, diluted with the lachrymal secretion, greatly exceeds in quantity that derived from any gonorrhœa. Although, says Dr. Vetch, the tumefaction may be at first farther advanced in one eye than the other, it generally reaches its greatest height in both about the same. The patient now begins to suffer attacks of excruciating pain in the eye; a certain indication of the extension of the mischief. "An occasional sensation, as if needles were thrust into the eye, accompanied with fulness and throbbing of the temples, often precedes the deeper-seated pain." This last is often of an intermitting nature, and a period of excruciating torture is succeeded by an interval of perfect ease. Sometimes, the pain shifts instantaneously from one eye to the other, and is seldom or never equally severe in both at the same time; and sometimes, instead of being in the eye, it occurs in a circumscribed spot of the head, which the patient describes by saying he can cover the part with his finger. Sooner or later, one of these attacks of pain is terminated by a sensation of rupture of the cornea, with a gush of scalding water, succeeded by immediate relief to the eye, in which this event has happened, but generally soon followed by an increased violence of the symptoms in the other. At length, the attacks of pain become shorter and less severe, though they do not cease altogether till after the lapse of many weeks and even months. *During this stage of the disease*, according to Dr. Vetch, *there is seldom the slightest alteration of the pulse, unless the lancet have been freely employed.* The patient's general health is little impaired, his appetite continues natural, but sleep almost totally forsakes him.

As the pain abates, the external tumefaction also subsides, and a gaping appearance of the eyelids succeeds; their edges, instead of being inverted, now becoming everted. This is what Dr. Vetch designates as the third stage of the disease.

After the swelling of the second stage has subsided, the eyelids are prevented from returning to their natural state by the granulated change of the conjunctiva which lines them; and an eversion of them now occurs in a greater or less degree.—(*Vetch on Diseases of the Eye*, p. 196. 202.) Among other interesting remarks made by the same author, he states, that there is no reason to warrant the idea that the ulceration ever proceeds from within outwards. He observes, that when any large portion of the cornea sloughs, an adventitious and vascular membrane is often produced, which finally forms a staphyloma. In some few cases, (says he), I have seen the lens and its capsule exposed without any external covering whatever, and, for a short time, the patient saw every thing with wonderful accuracy; but, as soon as the capsule gives way, the lens and more or less of the vitreous humour escape, the eye shrinks, and the cornea contracts into a small horn-coloured speck." This total destruction of the globe of the eye is said generally to ensure the other, and renders it less liable to be affected by future attacks of inflammation.

A few years ago an ophthalmy, supposed to be of the same nature as the Egyptian, though milder, like that which has generally been observed in schools, occurred to a great extent in the Royal Military Asylum at Chelsea, and Sir Patrick M'Gregor, the surgeon, favoured the public with an excellent description of the disease, and some highly interesting facts and reflections upon the subject. The symptoms generally made their appearance in the following order: "A considerable degree of itching was first felt in the evening; this was succeeded by a sticking together of the eyelids, principally complained of by the patient on waking in the morning. The eyelids appeared fuller externally than they naturally are; and on examining their internal surface this was found inflamed. The sebaceous glands of the tarsi were considerably enlarged, and of a redder colour than usual. The caruncula lachrymalis had a similar appearance.

"In 24 or 30 hours after the appearance of the above mentioned symptoms, a viscid mucous discharge took place from the internal surface of each eyelid, and lodged at the inner canthus, till the quantity was sufficient to be pressed over the cheek by the motions of the eye. The vessels of the tunica conjunctiva covering the eyeball were distended with red blood, and the tunica conjunctiva was generally so thickened and raised as to form an elevated border round the transparent cornea. This state was often accompanied with redness of the skin around the eye; which sometimes extended to a considerable distance, and resembled in colour and form very much what takes place in the cow-pox pustule, between the ninth and twelfth days after inoculation.

"When the purulent discharge was considerable, there was a swelling of the external eyelids, which often prevented the patient from opening them for several days. The discharge also frequently excoriated the cheeks as it trickled down. Exposure to light caused pain. When light was excluded, and the eye kept from motion, pain was seldom much complained of.

"These symptoms in many subsided without much aid from medicine, in 10, 12, or 14 days; leaving the eye for a considerable time in an irritable state. In several, however, the disease continued for a much longer time, and ulceration took place on the internal surface of the eyelids, and in different parts on the eye-ball. If one of those small ulcers happened to be situated on the transparent cornea, it generally, on healing, left a white speck, which, however, in the young subjects under our care, was commonly soon removed. In some few instances an abscess took place in the substance of the eyeball, which, bursting externally, produced irrecoverable blindness."—(See *Trans. for the Improvement of Med. and Chir. Knowledge, vol.* 3, *p.* 31—40.)

When the local symptoms had prevailed two or three days, some febrile disturbance occurred; but, except in severe cases, it was scarcely observable.

Sir P. M'Gregor considered this ophthalmy to be of the same nature as that which raged with such violence in the army at different periods, after the return of our troops from Egypt in 1800, 1801, and 1802. However, he found that its consequences were not so injurious to children as to adults; for, out of the great number of children afflicted with the disease at the Military Asylum, only six lost the sight of both eyes, and twelve the sight of one eye.—(*Op. cit. p.* 49.) On the other hand, Dr. Vetch informs us, that in the second battalion of the 52d regiment, which consisted of somewhat more than 700 men, 636 cases of ophthalmia were admitted into the hospital between August, 1805, and August, 1806; and that "of this number, fifty were dismissed with the loss of both eyes, and forty with that of one." And as Sir P. M'Gregor observes, it is a melancholy fact, as appears from the returns of Chelsea and Kilmainham hospitals, that 2317 soldiers were, on the 1st of December, 1810, a burden upon the public, from blindness in consequence of ophthalmia. The cases in which only one eye was lost are not here included.

The attacks of the disease appear to be much more frequent, severe, and obstinate, in hot sultry weather, than in cold or temperate seasons.—(*Op. cit. p.* 37. 54, *&c.*)

Sir P. M'Gregor also observed, that the ophthalmy was more severe and protracted in persons of red hair or a scrofulous habit than in others. The right eye was more frequently and violently affected than the left. In females, the symptoms were greatly aggravated for some days previous to the catamenia; but on this evacuation taking place, they were quickly lessened. Sir P. M'Gregor farther remarked, that the measles, cow-pox, and mumps went through their course as regularly in persons affected with this species of ophthalmia, as when no other disease was present; a circumstance which, with some others, prove that the disorder was entirely local.—(*P.* 54, 55.)

With respect to the causes of the *Egyptian Purulent Ophthalmy*, much difference of opinion has prevailed, and indeed there was a time when the disease was regarded by the majority of army-surgeons, who alone had opportunities of judging of it, as not being in reality *contagious*, but *dependent upon local epidemic causes; the irritation of sand; peculiarity of climate, &c.* The late Mr. Ware even doubted the propriety of calling this ophthalmy *Egyptian*, and he contended that a disease, precisely similar in its symptoms and progress, had been noticed long ago in this and other countries; and that, in Egypt, several varieties of ophthalmy prevail. He preferred calling the disease the *Epidemic Purulent Ophthalmy*. On the other hand, Sir W. Adams conceives, that it ought rather to be called *Asiatic Ophthalmy*, as recent investigations prove that it prevails in the greater part of Asia, and was long ago described by Avicenna.—(*Graefe, Journ. der Chir. b.* 1, *p.* 170.)

That there has been long known in this country an infectious species of purulent ophthalmy, cannot be doubted. The case described by many surgeons, as proceeding from the sudden stoppage of gonorrhœa, or the inadvertent application of gonorrhœal matter to the eyes, which disorder will be presently noticed, is certainly an infectious purulent ophthalmy. It is also admitted, that it resembles Egyptian ophthalmy, by the intensity and rapidity of its symptoms; but the latter case is strongly characterized by the quickness with which it causes, especially in adults, opacities, or ulcerations of the cornea; the long-continued irritability of the eyes after the subsidence of inflammation; but more particularly its very *infectious* nature, by which it spreads to an extent *that has never been observed with regard to any other species of purulent ophthalmy* There have been epidemic ophthalmies of other kinds, which have been known to affect the greater part of the population of certain districts and towns in England. The celebrated ophthalmy which happened at Newbury, in Berks, some years ago, is an instance that must be known to every body. But I know of no *purulent* inflammation of the eyes, which ever spread to a great extent in England, before the return of our troops from Egypt.

The reflections and observations of Sir P. M'Gregor, as well as those of Dr. Vetch and Dr. Edmonstone, I think, leave no doubt of two facts: first, that this ophthalmy was at all events brought from Egypt; and, secondly, that it is infectious, *but only capable of being communicated from one person to another by actual contact of the discharge.* "If (says Dr. Vetch) any belief were entertained by the officers of the British army, during the first expedition to Egypt, that the disease was contagious, it was of a nature very vague and indefinite. Combined as its operations necessarily must be in that country *with other exciting causes*, there would be more difficulty in the first recognition of the fact. But the continuance of the complaint with the troops after their departure from the country, could scarcely fail to lead to the obvious conclusion of its possessing a power of propagation. Before the disease reached this country, the opinion of its being contagious was adopted by many. *Dr. Edmonstone*, in the account which he published of the disease as it appeared in the regiment to which he was surgeon after its return to England, *first made the public acquainted with the fact of the disease being communicable.* In an account of the Egyptian ophthalmia, as it appeared in this country, printed in the early part of 1807, *I first established, that the communication of the disease was exclusively produced by the application of the discharge from the eyes of the diseased to those of the healthy.*"—(*On Diseases of the Eye, p.* 178.)

The opinion, that the disease is ever communicated from one person to another, through the medium of the atmosphere, is at present nearly abandoned. During the whole time that Dr. Vetch had the management of the ophthalmic hospitals, there never was an instance of any medical officer contracting the disease, although exposed to what might be supposed to be the greatest concentration of any contagion that could arise in the worst stage of the complaint. Two orderlies only contracted the disease, and both in consequence of the accidental application of the virus. However, Sir W. Adams maintains, that he has seen many cases, which prove that the disorder, like small-pox, may spread contagiously without any kind of inoculation.—(See *Graefe's Journ. b.* 1, *p.* 174.) That the disease may also be partly propagated by epidemic causes in particular situations, I think as certain and clear, as that there must be a cause for the first commencement of the disorder in situations where infection by contact is out of the question. And as Dr. Vetch has observed, "from whatever cause inflammation of the conjunctiva may originate, when the action is of that nature, or degree of violence, as to produce a puriform or purulent discharge, the discharge so produced operates as an animal virus, when applied to the conjunctiva of a healthy eye. Considering the various modes by which such a contact must inevitably occur in the usual relations of life, it must be obvious, that wherever ophthalmia prevails, whether it be the effect of local conditions of the soil or of the atmosphere, naturally or artificially produced, this contagious effect must sooner or later mix or unite its operation with that of the more general and original one: and hence, without regard to this property of the disease, its occurrence must often remain inexplicable, and at variance with the more general cause existing in external circumstances. And, farther, as the disease produced by infection is of a nature more violent and malignant than that produced by the impression of atmospheric causes, it will, in every instance of extensively-prevailing ophthalmia, occasion two different forms of disease, which, as long as they are considered as one and the same, will produce, according as the one or the other predominates, very discordant results."—(*On Diseases of the Eye, p.* 175.)

Sir P. M'Gregor relates three cases, which prove that the matter, after its application, produces its effects in a very short time. I shall only cite the following example.—On the 21st of October, 1809, about four o'clock, P. M., Nurse Flannelly, while syringing the eyes of a boy, let some of the lotion which had already washed the diseased eyes pass out of the syringe into her own right eye. She felt little or no smarting at the time; but towards nine o'clock the same evening, her right eye became red and somewhat painful, and when she awoke next morning, her eyelids were swelled, there was a purulent discharge, pain, &c.—(*Op. cit. p.* 51.)

The late Mr. Ware, though he admitted that the infection was brought into this country from Egypt by the troops, conceived that the same disease also sometimes arose from the matter of gonorrhœa being applied to the eyes, and that it had been prevalent in this country before the return of the army from Egypt. He thought, however, that the infection was generally communicated by contact. Mr. Ware observes, some of the worst cases of the purulent ophthalmy of children have happened in those whose mothers were subject to an acrimonious discharge from the vagina at the time of parturition. Some of the worst forms of the purulent ophthalmy in adults have occurred in those who, either shortly before the attack of the ophthalmy or at that very time, laboured either under a gonorrhœa or a gleet. Mr. Ware does not mean to impute every purulent ophthalmy to such a cause; but in the majority of adults whom he has seen affected, if the disorder had not been produced by the application of morbid matter from a diseased eye, it could be traced to a connexion between the ophthalmy and disease of the urethra. Other causes, Mr. Ware acknowledges, may contribute to aggravate, and, perhaps, produce the disorder, and the purulent ophthalmy in Egypt has been attributed to a great number. The combined influence of heat and light, of a burning dust, continually raised by the wind, and of the heavy dews of the night, may powerfuly tend to excite inflammations of the eyes. Yet something more must operate in causing the malignant ophthalmy now under consideration; for the same causes operate with equal violence in some other countries besides Egypt, and yet do not produce the same effect; and in this country (says Mr. Ware), the disorder prevailed during the last summer to as great a degree, and upon as great a number of persons, within a small district of less than a mile, as it ever did in Egypt; and yet, beyond this space on either side, scarcely a person was affected with it. The disorder was certainly brought into this country by the soldiers who returned from Egypt, and was probably communicated from them to many others. Now, as the action of the atmosphere alone cannot account for the spreading of the disease, &c., Mr. Ware is led to believe, that this particular disorder is only communicable by absolute contact; that is, by the application of some part of the discharge which issues either from the conjunctiva of an affected eye, or from some other membrane secreting a similar poison, to the conjunctiva of the eye of another person. In schools and nurseries, in consequence of children using the same basins and towels as others who had the complaint, the disease has been communicated to nearly twenty in one academy. Hence, Mr. Ware censures the indiscriminate use of those articles in schools, nurseries, hospitals, ships, and barracks.—(*P.* 14, 15.)

That in Egypt the origin of the disease cannot rightly be imputed to the effect of the sand and hot winds of the country is clearly proved; 1st. Because, if this were the case, the disease would not be most prevalent in the autumnal season during the inundation of the Nile. 2dly. The inhabitants of the Delta would not be more subject to it than the Bedouin Arabs, who live on the sands of the desert. Not only the Bedouin Arabs, says Dr. Vetch, remain free from the disease, but Europeans *who are not particularly exposed to the night air, are also safe from its attacks.*" The nature of military duty prevented our soldiers from using this precaution, and in a particular manner they became victims to the complaint. The men suffered more in proportion to the officers of the English army; as the latter enjoyed a better though often an incomplete defence from the coldness and dampness of the night; and officers employed in strictly military duty suffered more than those attached to the civil departments."—(*Vetch on Diseases of the Eyes, p.* 157.) And Assalini remarks, that if the dust or sand were the sole cause of ophthalmia, we ought to be exempted from the disease where the cause does not exist. The contrary, however, was the case in the Delta, and principally on the cultivated borders of the Nile during its inundations. *When we were exposed to the air during the night, we were immediately attacked with ophthalmia,* though the dust and sand were then under water Larrey also imputes the origin of the disease to the cold, damp nocturnal air after the great heats of the day.—(*Graefe's Journ. b.* 1, *p.* 179.)

Whoever reads the account of the Egyptian ophthalmia, as given by Sir P. M'Gregor and Dr. Vetch, will be convinced, that the disorder is only communicable from one person to another by the application of the infectious matter to the eyes. Probably the common mode of propagation is the inadvertent use of the same towels, or even merely touching the same articles which have been in the hands of infected persons, who must be supposed occasionally to apply their fingers more or less to the eyelids. In this last way, the commencement of the disease may be accounted for in regiments upon their entering into barracks which have been quitted by other infected soldiers. "Flies, in warm weather (says Sir P. M'Gregor), are seen in great numbers surrounding patients labouring under ophthalmia; and I much suspect are very frequently the medium by which the disease is communicated."—(*P.* 54.) The matter is observed to be most infectious when the disease is in an acute state.

Dr. Vetch adverts to two important questions, connected with the history of the Egyptian ophthalmy The first relates to the length of time which the disease has, at different periods, lain dormant, and especially between the return of the troops from Egypt and the breaking out of the disease in the 52d regiment. An explanation of this fact is attempted by supposing that the complaint exists, and is liable to a renewal of its infectious quality, long after the eye seems to have recovered its natural and healthy appearance. Perhaps it would be as well to be content with the fact, that in crowded barracks, under particular circumstances, soldiers who have once had the disease are very liable to relapses. The other question is, why has the disease produced such ravages in the army in England, and not in that of France? It is well known that the French soldiers in Egypt suffered as much as our own troops from the affection, and great numbers of them returned to France with the disease in a chronic form. "In many (says M. Roux) the influence of their native climate has sufficed for the removal of all vestige of the disorder. On the contrary, in others it has continued in a chronic state, either attended with the loss of one or of both eyes: and many of our invalids remain with the affliction. But it has not been found, that those soldiers who returned from Egypt have ever communicated a contagious ophthalmia, either in regiments in which many of them have been incorporated, or in invalid houses, where others have obtained their retirement, or in the individuals belonging to the different classes of society. Such is the objection that has been made, and may always be again urged, against the opinions and remarks of the English, respecting the Egyptian ophthalmy."—(*Voyage faite à Londres en* 1814, *ou Parallèle de la Chir. Angloise, &c. p.* 49.)

Larrey, who admits that the disease may be communicated by application of the matter, argues that it is not contagious in any other way, because, in Egypt, for want of sufficient hospital room, patients with this and other diseases were mixed together without the ophthalmia being propagated to any of the patients, who were careful to avoid the above mode of infection. —(*Graefe's Journ. b.* 1, *p.* 179.) Larrey, however need not have used this reasoning with us, because it is a mistake in him to suppose, that the disease is here commonly regarded as communicable through the medium of the atmosphere. While, however, English surgeons chiefly explain the extension of the disease by the infectious nature of the discharge when applied to the eyelids, and Larrey admits that the matter is thus infectious, the latter, as well as Roux, assures us, that none of the healthy soldiers who came home with the blind invalids from Egypt were attacked with this species of ophthalmy. A great number of those invalids were received in the hospital of the guards at

Paris, and treated there without any of the other patients being infected.—(*Graefe's Journ. loc. cit.*) On my return from the Mediterranean through France, in 1802, I saw many of the French troops at Aix and Avignon with bad eyes, contracted in Egypt, associating with other soldiers, whose eyes were perfectly healthy, and living in the same barracks; a proof that the French soldiers, with the exception of climate, or some other protecting cause, were placed apparently in circumstances in which the disease here made such extensive ravages. This is a point which I humbly conceive is not at all solved by Dr. Vetch's belief, that the difference is explicable by the French troops being sent into the field; for, in fact, the soldiers with diseased eyes were in barracks or hospitals as well as our own troops.

But notwithstanding it seems proved, that the discharge from the eyes in the Egyptian ophthalmy is so actively infectious in England, it appears from an experiment, made by Mr. Mackesy, that its application may sometimes be made to a healthy eye without the disease following as a matter of certainty; for he applied to his own eyes linen impregnated with matter discharged from the eyes of patients in the fully formed stage of the disease, and even allowed some of the matter to pass under the eyelids; yet the complaint was not communicated.—(See *Edinb. Med. and Surg. Journ. vol.* 12, *p.* 411.)

One of the most material circumstances in which the practice of English surgeons differs from that of foreign practitioners in cases of severe purulent and especially Egyptian ophthalmy, is the freedom and boldness with which the former attack the disease in its first stage. Mr. Peach recommends taking away at once as much as 60 ounces of blood (*Edinb. Med. and Surg. Journ. for January*, 1807); and Dr. Vetch lays great stress on the striking benefit of bleeding the patient till syncope is produced. "When inflammation has its seat in the sclerotic coat (says he), general blood-letting may for the most part be dispensed with, and even when employed to the greatest extent, the same benefit does not ensue. In the purulent inflammation of the conjunctiva, however, although some good may be derived from depletion, yet a perfect command over the disease depends less on lowering the system than on the temporary cessation of arterial action by syncope, which it becomes the object of the operation to produce. This practice, besides its efficacy, will accomplish the cure with a much less expenditure of blood than is occasioned by the repeated bleedings generally had recourse to where this method of rendering one equal to the cure of the complaint has been neglected. Some time before the approach of faintness the redness of the conjunctiva for the most part disappears; but this is no security against the return of the disease, if the flow of blood be stopped, without deliquium animi succeeding."—(*On Diseases of the Eye, p.* 206.) The attacks of a painful sensation, as if gravel were in the eye, he considers as a proof of the disease increasing, and, in the early stage of the disease, as a better indication of the necessity for bleeding, than the appearance of the eye itself.

With respect to applications, Dr. Vetch speaks very highly of the beneficial effects produced in the beginning of the case by dropping into the eye the undiluted liquor plumbi subacetatis, which, he says, diminishes the discharge, lessens the inflammation, and is incapable of doing harm in any stage of the disease. He places great confidence in the salutary results of a free exposure of the eye to the atmosphere; and speaks in high terms of the good derived from applying at night to the eye an infusion of tobacco, two drachms of the leaves to eight ounces of water. "It possesses (says Dr. Vetch) the valuable properties of acting as a powerful astringent, restraining the purulent discharge, and diminishing the œdema or external swelling of the palpebræ; at the same time that its narcotic qualities often relieve the pain and the perpetual watchfulness which the largest doses of opium cannot subdue."—(*P.* 211.) Bleeding, however, is the "sheet anchor," and the only means of preventing the destruction of the cornea, whenever attacks of pain in the eye or orbit denote the unsubdued state of the disease.—(*P.* 212.) When the disease shifts its violence from one eye to the other, and is of long duration, Dr. Vetch recommends cupping, and the eye to be more carefully cleaned by the injection of tepid water or any gentle astringent lotion, and afterward wiped dry. When the discharge continues acrid and scalding, he directs blisters to be applied to the nape of the neck and behind the ears. He wishes it to be distinctly kept in mind, that the time for the employment of bleeding, with the view of saving the eye, is during the first stage, or early part of the second; and when ulceration of the cornea has commenced, the case is to be treated on the principles applicable to sclerotic inflammation.

With regard to the plan of diminishing inflammatory action by medicines which excite nausea and sickness, instead of having recourse to the lancet, Dr. Vetch states, that in soldiers it does not answer so well, and in the end proves more debilitating.

As soon as the external œdema of the eyelids subsides, and they begin to be everted, Dr. Vetch represses the granulations and general villosity, by a very light and careful application of the argentum nitratum. The everted portion is then to be returned, and secured in its place with a compress and bandage. This method is to be repeated every time the eye is cleaned, and in the course of a fortnight the tendency to ectropium will be removed.—(*P.* 229.)

Assalini found venesection, all emollient applications, and eyewaters hurtful. He first purged his patients, and then introduced into their eyes a few drops of a solution of the lapis divinus (see *Lachrymal Organs*), to which was sometimes added a small quantity of the acetate of lead. He speaks favourably of leeches, and sometimes he put a small blister on the temple or behind the ears.—(See *Manuale di Chirurgia; Milano*, 1812.)

Perhaps the best mode of putting an immediate stop to the Egyptian ophthalmy, when it prevails extensively in a regiment in garrison or barracks, is to put the men actually affected into a detached hospital at a considerable distance from the rest of the corps, which should be dispersed as much as possible in separate billets and villages. Purulent ophthalmy is a disease which makes great progress only when large numbers of persons are either exposed together to the epidemic causes which first give birth to it, or to the causes which occasion the disease to be communicated from one individual to another, as when soldiers are crowded together in the same building, using the same towels and water, &c. Notwithstanding the reports of Roux and Larrey prove that the disease did not spread in the French army, after the return of uncured soldiers from Egypt to France, though these were freely mixed with their comrades in hospitals and barracks, the same security did not extend to the British troops of the army of occupation in that country in 1816, who were threatened with a very extensive renewal of the Egyptian ophthalmy among them, but which was wisely checked by attention to the principles above specified, and in which Sir James Grant, the head of the medical department of that army, had the greatest confidence.

In the cases under Sir P. M'Gregor, local applications were found most advantageous. During the inflammatory stage, however, this gentleman also had recourse to antiphlogistic means, spare diet, bleeding, neutral salts, &c. The topical treatment was as follows: leeches were freely and repeatedly applied near the eye. But while there was much surrounding redness, instead of leeches, which created too much irritation, fomentations with a weak decoction of poppy heads, and a little brandy, were used. A weak solution of acetate of lead and sulphate of zinc had mostly a good effect when applied to the eye. The vinous tincture of opium did not answer the expectations entertained of it. But of all the remedies, the ung. hydrarg. nitrat. was found most frequently successful. It was applied by means of a camel-hair pencil, and at first weakened with twice its quantity of lard. The red precipitate, well levigated, and mixed with simple ointment, sometimes answered when the ung. hydrarg. nitrat. failed. Well-levigated verdigris, and a quack medicine called the golden ointment, proved also sometimes efficacious.—(*P.* 41—43.) According to Sir P. M'Gregor, blisters behind the ears and upon the neck are useful; but hurtful when put nearer to the eye. In cases where the disease seems to resist antiphlogistic means, and ulceration has commenced on the external surface of the cornea, this gentleman approves of discharging the aqueous humour by a puncture, as advised by Mr. Wardrop.

When the violence of the inflammation has subsided, Sir P. M'Gregor recommends the use of Bates's camphorated water, diluted with four, five, or six times its quantity of water. But the astringent collyrium, from which he saw most good derived, was a solution of the nitrate of silver, in the proportion of half a grain to every ounce of distilled water. In some cases it may be used stronger.

Tepid sea-water sometimes proved serviceable in removing the relics of the complaint.—(*P.* 56, *&c.*)

Purulent Ophthalmy of Infants. Dr. Vetch describes the external appearances of this case as not materially different from those of the purulent ophthalmy of adults; but he states, that its nature is considerably modified by the more delicate texture and greater vascularity of the parts affected, and the more intimate connexion subsisting between the vessels of the conjunctiva and those of the sclerotic coat. Hence, he says, the inflammation is sooner communicated to this coat, and sloughing and ulceration of the cornea occur earlier in infants than adults. When the œdema ceases, the inner surface of the palpebræ becomes sarcomatous, and this diseased surface, when the eyelids are opened, forms an exterior fleshy circle, beyond which the relaxed conjunctiva of the eye comes forwards as a second; and often the caruncula lachrymalis adds still farther to the valvular appearance which the part presents.—(*On Diseases of the Eye*, *p.* 256—258.)

According to the late Mr. Ware, the principal difference between the purulent ophthalmy in infants and that in adults, consists in the different states of the tunica conjunctiva: in the former, notwithstanding the quantity of matter confined within the eyelids is often profuse, the inflammation of the conjunctiva is rarely considerable, and whenever the cornea becomes impaired, it is rather owing to the lodgement of such matter on it than to inflammation; a statement which appears to me very questionable. But in the purulent ophthalmy of adults, the discharge is always accompanied with a violent inflammation, and generally with a tumefaction of the conjunctiva, by which its membranous appearance is destroyed, and the cornea is made to seem sunk in the eyeball.—(*Ware on Epidemic Purulent Ophthalmy*, *p.* 23.) In children, the affection of the eyes is occasionally accompanied with eruptions on the head, and with marks of a scrofulous constitution.—(See *Ware*, *p.* 138, *&c.*) The only inference to be drawn from this fact is, that scrofulous as well as other children are liable to this disorder of the eyes.

The following is the treatment recommended by Mr. Ware. If the disease be in its first stage, the temporal arteries are to be opened, or leeches applied to the temples, or neighbourhood of the eyelids, and a blister put on the nape of the neck or temples. The child should be kept in a cool room, not covered with much clothes, and, if no diarrhœa prevail, a little rhubarb or magnesia in syrup of violets should be prescribed.

A surgeon, however, is seldom called in before the first short inflammatory stage has ceased, and an immense discharge of matter from the eyes has commenced. Of course, says Mr. Ware, emollient applications must generally not be used. On the contrary, astringents and corroborants are immediately indicated, in order to restore to the vessels of the conjunctiva and eyelids their original tone, to rectify the villous and fungous appearance of the lining of the palpebræ, and thus finally to check the morbid secretion of matter. For this purpose, Mr. Ware strongly recommends the *aqua camphorata* of Bates's Dispensatory: ℞. Cupri sulphatis, bol. armen. ā ā ʒiv. Camphoræ ʒj. M. & f. pulvis, de quo projice ʒj. in aquæ bullientis ʒiv. amove ab igne, et subsidant fœces. Mr. Ware, in his late *Remarks on Purulent Ophthalmy*, 1803, observes, that he usually directs the aqua camphorata, as follows: ℞. Cupri sulphatis, bol. armen. ā ā gr. viij. Camphoræ gr. ij. Misce, et affunde aquæ bullientis ʒviij. Cùm totio sit frigida, effundatur limpidus liquor, et sæpissimè injiciatur paululum inter oculum et palpebras. This remedy possesses a very styptic quality; but, as directed in Bates's Dispensatory, it is much too strong for use before it is diluted; and the degree of its dilution must always be determined by the peculiar circumstances of each case. Mr. Ware ventures to recommend about one drachm of it to be mixed with an ounce of cold clear water, as a medium or standard, to be strengthened or weakened as occasion may require.—(*P.* 143.) The remedy must be applied by means of a small ivory or pewter syringe, the end of which is a blunt-pointed cone. The extremity of this instrument is to be placed between the edges of the eyelids in such a manner that the medicated liquor may be carried over the whole surface of the eye. Thus the matter will be entirely washed away, and enough of the styptic medicine left behind to interrupt and diminish the excessive discharge. According to the quantity of matter, and the rapidity with which it is secreted, the strength of the application, and the frequency of repeating it, must be regulated. In mild recent cases the lotion may be used once or twice a day, and rather weaker than the above proportions; but, in inveterate cases, it is necessary to apply it once or twice every hour, and to increase its styptic power in proportion; and when the complaint is somewhat relieved, the strength of the lotion may be lessened, and its application be less frequent.

"The reasons for a frequent repetition of the means just mentioned, in bad cases, are, indeed, of the most urgent nature. Until the conjunctiva is somewhat thinned, and the quantity of the discharge diminished, it is impossible to know in what state the eye is; whether it is more or less injured, totally lost, or capable of any relief. The continuance or extinction of the sight frequently depends on the space of a few hours: nor can we be relieved from the greatest uncertainty, in these respects, until the cornea becomes visible."—(*Ware*, *p.* 145.)

This author condemns the use of emollient poultices, which must have a tendency to increase the swelling and relaxation of the conjunctiva. If poultices are preferred, he particularly recommends such as possess a tonic or mild astringent property; as one made of the curds of milk, turned with alum and an equal part of unguentum sambuci, or axungia porcini. This is to be put on cold, and frequently renewed, without omitting the use of the injection.—(*Ware*, *p.* 147.)

When the secreted matter is glutinous, and makes the eyelids so adherent together that they cannot be opened after being shut for any length of time, the adhesive matter must be softened with a little fresh butter mixed with warm milk, or by means of any other soft oleaginous liquor, after the poultice is taken off, and before using the lotion.—(*P.* 147.)

If the eversion of the eyelids only occurs when the child cries, and then goes off, nothing need be done in addition to the above means. When, however, the eversion is constant, the injection must be repeated more frequently than in other cases; the eyelids put in their natural position after its use; and an attendant directed to hold on them with his finger, for some length of time, a compress dipped in the diluted aqua camphorata.—(*P.* 148.)

In some cases, when the inside of the eyelids has been very much inflamed, the tinctura thebaica, insinuated between the eye and eyelids, has been useful. If, after the morbid secretion is checked, any part of the cornea should be opaque, the unguentum hydrargyri nitrati, melted in a spoon, and applied accurately on the speck with a fine hair-pencil, or Janin's ophthalmic ointment, lowered and used in the same manner, may produce a cure, if the opacity be not of too deep a kind. When the local disease seems to be kept up by a bad habit, alteratives should be exhibited, particularly the black sulphuret of mercury, or small doses of calomel.

The treatment recommended by Dr. Vetch is as follows: if the inflammation have not extended to the conjunctiva of the eye, its farther progress may be checked by removing the infant to a healthy atmosphere, and washing the eye with any mild collyrium. Leeches are commended throughout the whole course of the complaint. On the first accession of the tumefaction, the best effect will often be produced by the application of a small portion of ointment, composed of lard or butter ʒ vj., and x. gr. of the red nitrate of mercury, without any wax. As the purulency advances, the liquor plumbi subacetatis, he says, will be found not less serviceable than in other instances of purulent ophthalmy. For promoting the separation of any slough, he recommends a solution of the nitrate of silver; and for curing the relaxed state of the conjunctiva, a solution of alum, or of the sulphate of copper.—(*On Diseases of the Eye*, *p.* 260.)

The *purulent ophthalmy, arising either from suppression of gonorrhœa, or from the inadvertent conveyance of gonorrhœal matter to the eyes*, is said to produce rather a swelling of the conjunctiva than of the eyelids, which is followed by a discharge of a yellow greenish matter, similar to that of clap. The heat and pain in the eyes are considerable; an aversion to light prevails, and in some instances, an appearance of hypopion is visible in the anterior chamber of the aqueous humour. When the complaint proceeds from the second cause, it is described as being less severe than when it arises from the first. However, by such gentlemen (*Ware, Travers, &c.*) as have seen unequivocal instances of purulent ophthalmy excited in the second way, the disease is said to be remarkable for its violence and intensity. The reality of cases of purulent ophthalmy from the application of gonorrhœal matter to the eyes, seems supported by such a mass of evidence, that I believe the fact must be admitted. Yet, from some statements lately published by Dr. Vetch, it would appear, that the frequency of this mode of infection must be very much lessened by the circumstance of the matter taken from the urethra not being capable of communicating the disease to the eyes of the individual by whom such matter is secreted, though probably capable of doing so to the eyes of another person.

In the same way the urethra cannot be affected by the application of matter taken from the purulent eyes of the individual on whom the experiment is made. At least, of these circumstances there is a negative proof in some facts recorded by Dr. Vetch. "In the case of a soldier, received in a very advanced stage of the Egyptian ophthalmia, in whom destruction of the cornea had to a certain extent taken place, I took occasion to represent the possibility of diverting the disease from the eyes to the urethra, by applying the discharge to the latter surface. Accordingly, some of the matter taken from the eyes was freely applied to the orifice of the urethra. No effect followed this trial which was repeated on some other patients, all labouring under the most virulent state of the Egyptian disease, and in all the application was perfectly innocuous. But in another case, where the matter was taken from the eye of one man labouring under purulent ophthalmia, and applied to the urethra of another, the purulent inflammation of the urethra commenced in 36 hours afterward, and became a very severe attack of gonorrhœa. From the result of these cases (says Dr. Vetch) I could no longer admit the possibility of infection being conveyed to the eyes from the gonorrhœal discharge of the same person. Some time after this, the improbability, or rather impossibility, of this effect was rendered decisive by an hospital assistant, who conveyed the matter of gonorrhœa to his eyes, without any affection of the conjunctiva being the consequence."—(See *Vetch on Diseases of the Eye*, p. 242.) Hence, this gentleman is led to refer the connexion between gonorrhœa and ophthalmia in the same person, to peculiarity of constitution; but the theories on which this opinion rests, my limits will not allow me to examine.

If it be actually true that, in adults, a species of purulent ophthalmy does originate from the sudden suppression of gonorrhœa, are we to consider the complaint so produced as a metastasis of the disease from the urethra to the eyes? This ophthalmy does not regularly follow the suppression of gonorrhœa, nay, it is even a rare occurrence: also, when it is decidedly known that the purulent ophthalmy has arisen from the infection of gonorrhœa, namely, in those instances in which the matter has been incautiously communicated to the eyes, it appears that such an affection of these organs, so produced, is different from the one alluded to, inasmuch as it is slower in its progress, and less threatening in its aspect. When the eyes are affected, the disease of the urethra is not always suspended.—(*Vetch on Diseases of the Eye*, p. 239.) Hence, there is good reason for supposing that no metastasis takes place in this species of purulent ophthalmy, supposed to be connected with a suppressed gonorrhœa; but we must be content with inferring that, if it really has such a cause, it originates from a sympathy prevailing between the urethra and eyes; and that the difference of irritability in different people, is the reason why it is not an invariable consequence of the sudden stoppage of a gonorrhœa.

The injection of warm oil, the introduction of a bougie into the urethra, and the application of cataplasms to the perinæum, with a view of renewing the discharge from the urethra, form the outline of the practice of those who place implicit reliance in the suppression of gonorrhœa being the cause of the complaint. The rarity of the occurrence; the frequency of the sudden cessation of the urethral discharge; the possibility of an ophthalmy arising as well at this particular moment as at any other, totally independent of the other complaint, cannot fail to raise in a discerning mind a degree of doubt concerning the veracity of the assigned cause. Besides, admitting that there is a sympathy between the urethra and eyes, how are we to ascertain whether the suppression of gonorrhœa be the cause or the effect of the ophthalmy, supposing that the one ceases, and the other commences about the same time? Actuated by such reflections, I am induced to dissuade surgeons from adopting any means calculated to renew a discharge of matter from the urethra. When the purulent ophthalmy, in adult subjects, is decidedly occasioned by the actual contact and infection of gonorrhœal matter, applied accidentally to the eyes, no one has recommended this unnecessary and improper practice.

The first indication in the treatment of the disease from either cause, is to oppose the violence of the inflammation, and thus resist the destruction of the eye and opacity of the cornea. A copious quantity of blood should be taken away both topically and generally; mild laxatives should be exhibited, and a blister applied to the nape of the neck, or temples. The eyes ought to be often fomented with a decoction of white poppy-heads, and warm milk repeatedly injected beneath the eyelids. To prevent the palpebræ from becoming agglutinated together during sleep, the spermaceti cerate should be smeared on the margins of the tarsi every night.

When the heat and pain in the eyes, and febrile symptoms, have subsided; when an abundant discharge of pus has commenced; all topical emollients are to be relinquished, and a collyrium of aq. rosæ ℥ x. containing hydrarg. oxy. mur. gr. j. used in their place. Scarpa states, that in the ophthalmy originating from the inadvertent communication of the matter of gonorrhœa to the eyes, applications in the form of ointment, such as the ung. hydrarg. and Janin's salve, to which might be added the ung. hyd. nitrat., avail more than fluid remedies.

Inflammation of the Eyeball in general. From cases in which the eyelids are at first chiefly affected, I pass to the consideration of inflammation, as commencing in the eyeball itself. As Beer remarks, fortunately it is only very seldom that the whole of the organ is at once attacked with genuine idiopathic inflammation, without any part of its texture being spared. Although this kind of ophthalmy is far more frequent than common inflammation of the orbit, it is much more rare than the same disorder of the eyelids. For the most part, healthy inflammation of the eyeball has a limited point of origin, from which it spreads, sometimes quickly, sometimes slowly, over the whole organ. During an exceedingly violent, tense, throbbing pain, affecting not only the eye itself, but extending to all the surrounding parts, the bottom of the orbit, and within the head, the white of the eye becomes suffused with a uniform redness, which, on attentive examination, is found to be seated not only in the conjunctiva of the eyeball, but also in the sclerotica, and to exhibit at first a very fine vascular net-work, which, as the redness grows more intense, assumes the appearance of scarlet cloth, forming all round the cornea a uniform circular prominent fold, which has a very firm feel, and is so tender, that when touched in the gentlest manner, the patient cries out in agony. The circumference of the cornea continues to be more and more covered by this increasing swelling of the conjunctiva, until at length only a portion of its centre remains visible. At the same time, the pupil is very much contracted; the iris motionless; and though vision is nearly or entirely lost, the patient is seriously disturbed by fiery appearances before the eye. When the iris is naturally gray or blue, it turns greenish, and when brown or black, it becomes reddish. Every movement of the eyeball and upper eyelid is suspended, and the orbit feels to the patient as if it were too small, which, Beer says, is in reality the case, because the whole of the eyeball, and

not merely the conjunctiva is enlarged, so as to project like a lump of raw flesh farther and farther between the edges of the palpebræ, and completely fill every part of the orbit. While the eyeball enlarges, the cornea always loses its transparency, and the inflammation spreads to the eyelids, the lower one at last becoming everted by the excessive and firm tumefaction of the parts behind it, and the upper one presenting the most unequivocal marks of phlegmonous inflammation. The secretion of tears and mucus is now entirely suppressed, and of course the eye preternaturally dry. At the very commencement of this violent form of ophthalmy, the constitution is disturbed by a severe attack of inflammatory fever, and irritable patients are not unfrequently seized with delirium. Here, says Beer, terminates the first stage of this very dangerous disorder.

When the disease is left to itself, suppuration comes on, attended with fever and constant shiverings; the swelling of the sclerotic conjunctiva undergoes a remarkable increase, and assumes a dark-red colour at the same time that it becomes softer. The pain becomes irregular, throbbing, and when the eye or eyelids are touched, of a lancinating description. As a morbid secretion now begins to take place from the Meibomian glands, the swelled conjunctiva has a more moist appearance. The upper eyelid has a purple hue, and, on account of the continually-increasing size of the eyeball, is pushed farther and farther outwards. The portion of the cornea, still discernible in the middle of the protuberant conjunctiva, acquires a snowy whiteness, which afterward changes to yellow. The patient feels an oppressive sense of heaviness in the orbit, and a disagreeable kind of coldness all round the eye. At length, the throbbing and tension are so agonizing, that the patient often expresses a wish to have the eyeball extirpated. If no effectual treatment be adopted, the eye now bursts, and a mixture of matter and blood, together with the scarcely perceptible remains of the lens and vitreous humour, is discharged with considerable force to some distance in front of the patient; an occurrence, sometimes termed *rhexis* or *rhegma oculi*. From this moment, the pain all at once subsides into a very moderate feel of burning in the eye; and suppuration goes on until all the textures of the organ are annihilated, the orbit has an empty appearance, and the closed eyelids sink into a concavity. Thus ends, as Beer observes, the second stage, after much tedious and general indisposition. But he remarks, that the course of the case is quite different when it has been wrongly treated in its first stage with stimulants, or exposed to the ill effects of tobacco-smoke, the drinking of spirits, improper diet, immoderate exercise, &c.; for, under the operation of these unfavourable circumstances, the second stage may commence with dreadful gangrenous mischief, every vestige of the organization of the eye disappearing, and the parts at length sphacelating, while large abscesses form around, and, unless efficient medical aid be promptly given, the patient loses his life.

With respect to the causes of such an attack of the whole eyeball at once by common inflammation in a healthy subject, they must be of an exceedingly violent description, such as injuries produced by gunpowder, burns, and lesions either of a mechanical kind, or acting both chemically and mechanically together; a subject already fully treated of in the foregoing columns.

The following are the observations, which Beer delivers on the prognosis:—While, in the first stage of this dangerous form of ophthalmy, the eyesight yet remains, and the eyeball itself is not enlarged, if the patient can be properly taken care of, some hope may be entertained of dispersing the inflammation so favourably that, with the exception of a weakness of sight, of longer or shorter continuance, no ill effects will be left. It is manifest, however, that under these circumstances the surgeon should not be too bold in promising a perfect cure; for the very commencement of such an inflammation of the whole eyeball, even when the disorder is purely idiopathic, is unavoidably attended with some risk, not only of permanent blindness, but of the eye itself being destroyed in the most painful manner; and when things turn out rather better, a tolerably favourable termination of the case is uncommon. But as soon as the power of seeing is quite lost, the pupil nearly closed, and the eyeball prodigiously swelled, it will be fortunate if the inflammation can be resolved so as to preserve the shape of the organ; for the restoration of the eyesight is entirely out of the question. But besides the irremediable loss of vision, the disorder under these circumstances always produces a greater or less closure of the pupil, which, however, has no share in causing the blindness.

In the second stage of the case, of course, the hope of restoring vision is quite past, and if the eyeball itself, and not merely the conjunctiva, has been considerably swelled in the first stage of the case, the chance of preserving the natural shape of the organ is extremely unpromising. But when the eye bursts, the latter desideratum is impossible. If the first stage should have been so violent as to induce gangrene, the practitioner will have enough to do in preventing sphacelus and death; the danger of which is considerable, on account of the intimate connexion between the eye and parts in the orbit, and the brain and its membranes.

In the first stage, antiphlogistic treatment, in the general sense of the expression, is indicated, and the case is not to be regarded merely as a local disorder. However, with respect to topical bleedings, the surgeon, says Beer, should be more active than in other examples of ophthalmy, and, after copious venesection and the use of leeches have produced some relief, the protuberant conjunctiva round the cornea should be deeply scarified with a lancet. If in the first stage delirium come on, as it sometimes does during the violence of the inflammatory fever, Beer directs one of the external jugular veins to be opened: or blood might be taken from the temporal artery.

In the second stage of the case, when the re-establishment of vision is quite impossible, and the objects are to endeavour to keep the eye of a good shape, and quickly lessen the suppuration, warm emollient poultices, and particularly those made of apples, are the applications on which Beer bestows his praises. This topical treatment is to be assisted with internal means, as explained in the preceding pages, because the disorder is attended with a general disturbance of the constitution. When matter is fully formed, and its fluctuation can be distinctly felt, Beer approves of opening the abscess with a lancet; for it is only by this means that the annihilation of the eyeball can be prevented. If the eye has already burst, the preservation of its form is no longer possible, and according to Beer, both the topical and general treatment should be partly of a tonic description. When gangrenous mischief has occurred, the practice ought to conform to the principles explained in the article *Mortification*.

External Ophthalmy. Inflammation of the Outer Coats of the Eye. Ophthalmitis Externa Idiopathica, of Beer. The modifications of this common species of ophthalmy, as the latter author observes, have a variety of names applied to them, as *ophthalmia levis*, *ophthalmia angularis*, *taraxis*, and sometimes *chemosis*, and *ophthalmia sicca*. Together with a preternatural dryness of the eye, and a sensation as if the eyeball were compressed on every side, the white of the eye becomes covered with a general redness, which, though it affect both the sclerotica and the conjunctiva, will be found on attentive examination to be much more considerable in the former than the latter membrane, in which only a delicate plexus of blood-vessels is at first perceptible. The motions of the eye and eye lids are not absolutely prevented; yet the patient never moves these parts, except when he is actually obliged to do so, as every motion of them, if not actually painful, occasions a good deal of annoyance. Though the cornea cannot be said to become opaque, its clearness is always much diminished; and this change is the greater the redder the white of the eye appears. These effects, which occur almost simultaneously, are followed by pain, which increases every moment, at first extending over the whole eyeball, and then to the surrounding parts, and to the top of the head. As the pain grows more severe, every movement of the eyeball and palpebræ becomes more distressing, the dryness of the eye greater, and the redness of the sclerotic conjunctiva augments either more slowly or quickly, according to the degree of inflammation, until the net-work of blood-vessels, which was at first distinguishable, entirely disappears and the conjunctiva looks like a piece of red cloth, quite concealing the sclerotica, and forming round the cornea a very painful, firm, uniform, circular projection. Thus the cornea seems as if it lay in

a depression, with its margin partly covered by this inflammatory swelling of the conjunctiva. At the period when the protuberance of the latter membrane takes place, the cornea itself always becomes less and less clear, and of a reddish-gray colour, so that neither the iris nor the pupil can be any longer distinguished, and the power of vision is reduced to a faint perception of light. The pain, which was that of heaviness and tension, now becomes of a throbbing description, and the eyelids, which now begin to participate in the effects of the inflammation, are no longer capable of covering properly the swelled conjunctiva. The eyeball and eyelids are perfectly motionless; and if an attempt be made by the patient to move them, the efforts of the muscles may be perceived, but still no movement of the parts intended is performed. The orbit feels as if it were too small for the eye, and the constitution suffers a severe attack of inflammatory fever. Thus, says Beer, does the first stage of this form of ophthalmy gradually rise to its highest degree, to which he applies the name of *true chemosis*.

However, it is observed, that idiopathic external ophthalmy does not always become so violent; as, for instance, when the complaint has been excited merely by the lodgement of some small foreign body under the eyelids; for though, in such a case, the conjunctiva and sclerotica are both reddened together, yet even when no aid is afforded, if no other sources of greater irritation are present, the redness does not readily increase so as quite to conceal the sclerotica, or to be attended with an inflammatory swelling all round the cornea. This milder form of external ophthalmy has sometimes received the name of *taraxis*. It is the *mild acute ophthalmy* of Scarpa, characterized, as this author says, by redness of the conjunctiva and lining of the eyelids, an unnatural sensation of heat in the eyes, uneasiness, itching, and shooting pains, as if sand were lodged between the eye and eyelids. At the place where the pain seems most severe, Scarpa remarks, that some blood-vessels appear more prominent and turgid than other vessels of the same class. The patient keeps his eyelids closed; for he feels a weariness and restraint in opening them, and by this means he also moderates the action of the light, to which he cannot expose himself without increasing the burning sensation, lancinating pain, and effusion of tears. If the constitution be irritable, the pulse will be a little accelerated, particularly towards the evening; the skin dry; and sometimes slight shiverings and nausea and sickness take place.

According to Scarpa, mild acute ophthalmy is often the consequence of a cold, in which the eyes, as well as the pituitary cavities, fauces, and trachea, are affected. It is not unfrequently occasioned by change of weather, sudden transitions from heat to cold, the prevalence of easterly winds, journeys through damp, unhealthy, sandy countries, in the hot season of the year, exposure of the eyes to the vivid rays of the sun, draughts of cold air, dust, &c. Hence, it does not seem extraordinary that it should often make its appearance as an epidemic, and afflict persons of every age and sex. As additions to the list of remote causes, authors enumerate the suppression of some habitual evacuation, as bleedings from the nose, or piles, the menses, &c., a disordered state of the primæ viæ, worms, dentition, &c.

Between Beer and some late writers, there is either one point of difference in their descriptions of external ophthalmy, or else they mean different cases; for while Beer represents the redness as affecting the sclerotica at first more than the conjunctiva, other writers describe the affection of the sclerotica as generally secondary when it happens at all; for according to modern observations it is not *unavoidably* either an attendant upon or an effect of simple inflammation of the conjunctiva.

As the second stage of external ophthalmy comes on, the symptoms vary according to the degree of the complaint in its first stage; but when what Beer calls a *true chemosis* is produced, the following are described by him as the usual appearances. The circular prominent fold of the conjunctiva round the cornea becomes of a dark-red colour and the swelling increases, but it becomes softer and less painful. The hardly visible portion of the cornea, situated in the depression formed by the circular protuberance of the conjunctiva, seems at first perfectly white and afterward yellowish, being the seat of more or less purulent matter. Though the swelled conjunctiva is every where moistened with a thin whitish mucus, this secretion, says Beer, is never so copious as to run over the face, as in the case of ophthalmo-blennorrhœa. In this stage the lower eyelid is turned somewhat outwards, in consequence of its lining becoming more swelled. While suppuration is taking place in the cornea, attended with the febrile symptoms which usually accompany the formation of acute abscesses, little collections of matter sometimes occur at different points of the conjunctiva, and, after they have burst, a probe may easily be passed rather deeply into them without any particular pain.—(*Beer, b. 1, p.* 412.) The suppuration continually advancing, the swelling of the conjunctiva, and of the whole eyeball, now diminishes, the effects of the inflammation penetrate deeply into the organ, and the structure of the eye is so altered as not to be cognizable, the part shrivelling up, as Beer says, into a motionless whitish mass. However, according to this author these deep effects of suppuration are sometimes produced only in a certain part of the eyeball, especially when the chemosis is the consequence of an external injury; and in this circumstance the rest of the circumference of the globe of the eye exhibits its natural organization, while in the part above alluded to there is a funnel-like depression, attended with a considerable diminution in the size of the organ.

But, says Beer, when an idiopathic external inflammation of the eye has only attained the milder degree expressed by the term *taraxis*; as, for instance, when the complaint is principally owing to the lodgement of some mechanically or chemically irritating substance under the eyelids; the redness of the conjunctiva and sclerotica undergoes a remarkable increase on the accession of the second stage: the first of these membranes become somewhat swelled; the pain is lancinating and irregular, and the secretion of tears unusually profuse; but at the point where the extraneous substance lodges, an open superficial suppuration occurs, and, according to Beer, the case, both in the first and second stage, is generally accompanied with no febrile symptoms.

In the first stage, Beer represents the prognosis as very favourable, provided the disorder does not exceed that degree to which the name of *taraxis* is applied; for with the aid of proper treatment the inflammation, when of a healthy kind, may be soon so favourably removed as not to leave a vestige of it behind. If the cause of the disorder be not greater than a moderate injury or wound of the eye, any traces of the lesion which are, perhaps, still remaining, will disappear as soon as the inflammation subsides. On the other hand, when this kind of ophthalmy presents itself in the form of *true chemosis*, the prognosis is serious and must be made with great reserve, especially when the patient is of a weak irritable constitution, a child very stubborn and unmanageable, or incapable of following strictly the advice which he receives from his medical attendant; for under these circumstances it will not be in the power of the latter to prevent the complaint from advancing unremittingly to its second stage, in which event the ill consequences of suppuration will be incalculable. But if these unfavourable conditions are not present, though the genuine idiopathic chemosis may really have attained a violent and almost its highest degree in the first stage, not only the eye may be saved by prompt and judicious treatment, but also the eyesight; nor will the result be different even when the cornea continues for some time deprived of its transparency, and the power of vision impaired by a slight varicose affection of its conjunctival covering. These effects, says Beer, at length completely disappear, less in consequence of the aid of medicine than of a proper regimen, the uninterrupted enjoyment of a fresh dry air, &c.

The prognosis in the second stage, is under very different circumstances; for, as Beer observes, though the inflammation in the first stage may really not exceed that degree which is implied by the term *taraxis*, yet if any suppurating point occasioned by some slight preceding injury be not efficiently treated, or if there be any loss of substance already produced by the injury itself, a more or less opaque white cicatrix is apt to remain on the cornea, and cause a permanent impediment to vision in a degree determined by the situation and extent of the opacity. And in addition to this

risk, it is to be remembered, that if the suppurating point be entirely neglected, or erroneously treated, the cornea or sclerotica may be penetrated by ulceration, and, in the first case, a prolapsus of the iris, an adhesion of this organ to the cornea (synechia anterior), a disfigurement of the pupil, or an irregularity of the cornea, be produced; while, in the second, the consequences may be a partial wasting away of the eyeball, attended with loss of sight and of the natural shape of the part.—(*Beer, b.* 1, *p.* 417.)

Beer farther observes, that when this species of ophthalmy presents itself in its first stage in the form of *true chemosis*, the prognosis in the second stage is very unfavourable; for, when the cornea is generally pervaded by suppuration, the eyesight, and in some degree the form of the eyeball, are for ever lost, and it will be lucky if the case can be brought to a conclusion with the mere destruction of the cornea. But when the matter points at once in several places of the conjunctiva, round the cornea, all idea of preserving the shape of the eye sufficiently for the application of an artificial eye is out of the question, and the surgeon will be very successful if he can now check in moderate time the suppuration, which continues, with a good deal of general indisposition. An extraordinary relaxation of the conjunctiva of the lower eyelid, and a consequent ectropium, are the least disastrous effects of the abscesses of the eye thus produced. Lastly, Beer remarks, that when chemosis is in the second stage, that is to say, attended with suppuration of the eye, it rarely happens, under the most favourable circumstances, that the eyesight and shape of the organ can be preserved entirely free from permanent injury. —(*B.* 1, *p.* 418.)

Let us next consider the treatment of idiopathic external ophthalmy in its modifications of simple inflammation of the conjunctiva, mild acute ophthalmy, or taraxis, and severe acute ophthalmy, with chemosis.

According to Mr. Travers, simple inflammation of the conjunctiva, unconnected with injury of the eye, and neither depending upon any established disorder of the system, nor modified by a scrofulous diathesis, may be easily and speedily reduced, even in its most acute form, by bleeding, and some brisk doses of purgative medicine.—(*Synopsis of the Diseases of the Eye, p.* 247.) For the relief of mild acute ophthalmy, Scarpa recommends low diet, gentle purging, with small repeated doses of antimonium tartarizatum, the removal of any extraneous body lodged under the eyelid, and frequently washing the eye with a warm decoction of mallow-leaves, and covering it with a very soft emollient poultice, included in a fine little muslin bag. Mr. Travers also expresses his decided preference to a tepid application in the painfully acute stage of inflammation, and considers simple warm water generally better than medicated lotions, like the aqueous solution of opium, or infusions of poppy and hemlock.

When the disease presents itself in its first stage, in the mild form of taraxis, says Beer, it usually runs its course quite uncomplicated with any general indisposition, and may be cured by moderate antiphlogistic treatment, in which, indeed, since the eyeball itself is affected, particular attention must be paid to lessening the action of the light and air upon the organ. But when a true chemosis is present, every antiphlogistic means must be promptly and rigorously put in practice, internal as well as external remedies being employed, and, besides common measures, the conjunctiva, round the cornea, is to be scarified; a proceeding never necessary in the case of taraxis. Such scarifications, Beer observes, have a wonderful effect when practised at the proper period, after venesection and topical bleeding with leeches have been fully put in execution, and when the cuts are made deep, so as to produce immediately a copious discharge of blood. "By means of such scarifications (says he) I have seen the inflammation and all its threatening effects recede, as it were, before my face, when no material relief could be effected by other measures."—(*B.* 1, *p.* 419.) In this country, the best practitioners rarely have recourse either to incisions or scarifications in chemosis; and have more confidence in general than local treatment.—(*Welbank; note in Frick on Dis. of the Eyes, p.* 15, *ed.* 2)

Of the application of the vapour of ether, or of the juice of lettuces to the eye and eyelids, for the relief of chemosis, as recommended by Mr. Ware (*p.* 54), I shall only say, that they are plans which do not retain the approbation of modern practitioners.

General and local bleeding having been put in practice, the treatment is to be continued by administering purgatives of the mildest description, and after their operation applying blisters, according to the directions given in a preceding part of this article. In the first stage of severe acute ophthalmy, Scarpa considers topical emollient applications to the eye most beneficial: such as mallows boiled in new milk; bread and milk poultices; or the soft pulp of a baked apple; all included in fine little muslin bags. Remedies of this description should be renewed at least every two hours. The patient should be directed to observe perfect quietude, and to lie with his head in an elevated position. To keep the eyelids from adhering together in the night-time, the spermaceti cerate is proper. When ophthalmy is accompanied with a violent pain in the head, the late Mr. Ware recommended a strong decoction of poppy-heads as a fomentation.—(*P.* 51.)

Under the preceding plan of treatment, the first stage of severe ophthalmy commonly abates in about a week. The burning heat and darting pains in the eyes, and the febrile disturbance of the constitution subside. The patient is comparatively easy, and regains his appetite. The eyes become moist again, and can now be opened without experiencing vast irritation from a moderate light. In this state, notwithstanding they may continue red, and the conjunctiva swelled, all evacuations are to be left off, as well as the use of topical emollients, for which latter astringent, corroborant collyria are to be substituted. Scarpa recommends the following application: ℞. Zinci sulphatis gr. vj. Aquæ distillatæ ℥ vj. Mucil. sem. cydon. mali ℥ ss. Spiritûs vini camphor. guttas paucas. Misce et cola. This collyrium may be injected with a syringe, between the eye and eyelids, once every two hours; or the eye may be bathed in it, by means of an eye-cup. Such persons as cannot bear cold applications to the eye, must have the same kind of collyrium a little warmed; but as soon as the irritability is lessened, it may be used cold.

Scarpa then speaks of the good effects produced in the second stage of ophthalmy by the application to the eye of two or three drops of the vinous tincture of opium, once or twice a day; a subject already considered in the foregoing columns. The utility of letting the eye be habituated to the light as soon as it can bear it, is next strongly commended; a rule of great importance, but on which I need not here dwell, because it has been already insisted upon in the general observations.

When idiopathic external ophthalmy has terminated in suppuration of little extent, Beer speaks highly of the benefit derived from a solution of the lapis divinus (see *Lachrymal Organs*), containing the liquor plumbi subacetatis, or from smearing the suppurating points with a little laudanum. In worse cases, Beer states, that when such local treatment is combined with the internal exhibition of bark and naphtha, and a diet and regimen conducive to the support of the system, its efficacy is very great. And here, says he, it is worth observing, that while the solution of the lapis divinus is of great service in the second stage of *true chemosis*, it is more or less detrimental in the kind of chemosis which accompanies purulent ophthalmy, especially if not blended with mucilage, and even when thus qualified, it cannot be endured by weak and irritable subjects, affected with the latter complaint; a fact not observed in other instances of chemosis.—(*B.* 1, *p.* 420.)

When pustules or abscesses in the swelled conjunctiva point round the cornea, a free outlet to the matter must be immediately made in each of them with a lancet; for if this be not done, as Beer observes, the matter will spread extensively, and the eyeball be in danger of being destroyed. For an account of the method of treating the eversion of the lower eyelids, sometimes remaining as a consequence of the disorder, see *Ectropium*.

Inflammation of the Sclerotica. The modern attempts to class ophthalmies, according to the texture of the eye first or chiefly affected, promises, I think, to lead to clearer views of the subject, and sounder practice. One circumstance particularly adverted to, both

by Dr Vetch and Mr. Travers, in inflammation of the sclerotica, is the appearance of a vascular zone at the margin of the cornea. By the latter gentleman, this effect is ascribed to the particular distribution of the vessels. "Branches from the straight vessels of the conjunctiva penetrate the sclerotica obliquely towards the margin of the cornea, and the long ciliary vessels pass in sulci of this membrane to the plexus ciliaris at the root of the iris. At the interior border of the sclerotica, where the annulus ciliaris is adhering closely to this tunic, the ciliary communicate with the muscular branches, and being in deep-seated inflammation fully injected with red blood, the condensation of colour gives the well-known and remarkable appearance of a vascular zone at the margin of the cornea."—(*Synopsis, &c. p.* 126.) According to Dr. Vetch, only a few interspersed trunks are posteriorly observed, "which do not affect the natural appearance of the intermediate space, but these, diverging as they come forwards, produce a zone, more or less complete, of minute hair-like vessels, distinguished by their rectilinear direction, and their uniform concentration towards the margin of the cornea: their colour advances with the progress of the disease, from that of a delicate pink or damask rose to a deeper hue, and imparting a faint blush to the part immediately surrounding it."—(*On Diseases of the Eye, p.* 27.) There appears, however, to be a good deal of variety in the symptoms of sclerotic inflammation; for rheumatic inflammation of the eye, described by Beer and Wardrop, as particularly affecting the sclerotica, in common with other fibrous membranes, is not noticed by these authors as characterized by the red zone round the edge of the cornea. Indeed, instead of there being posteriorly only a few interspersed trunks, Mr. Wardrop states, "that (in rheumatic ophthalmy) the blood-vessels are generally *equally* numerous over the whole white of the eye, passing forwards in nearly straight lines from the posterior part of the eyeball, and advancing close to the cornea; but neither passing over it, *nor leaving the pale circle around it*, which is so *striking when either the choroid coat or iris is inflamed.* If the vessels be closely examined, the general redness will be found produced more from numerous small ramifications, than a few large trunks."—(*Med. Chir. Trans. vol.* 10, *p.* 3.) However, as if there must be no harmony on this subject, Beer describes the blood-vessels in rheumatic ophthalmy, not as being *equally* numerous over the whole white of the eye, but as being *in some places collected in larger numbers* or *clusters*, and he differs again from Mr. Wardrop, in describing the redness as coming on with considerable intolerance of light (*Lehre von den Augenkr. b.* 1, *p.* 397, 398), while the latter author distinctly mentions, that "the eye does not seem to suffer from exposure to light."—(*Med. Chir. Trans. vol.* 10, *p.* 6.) I can only reconcile these accounts by concluding that sclerotic inflammation, like that of other textures of the eye, has stages and modifications which account for these seeming contradictions. And with respect to the vascular zone round the edge of the cornea, it would appear, at all events, to belong to iritis, as well as sclerotic inflammation. The vessels of the sclerotic coat are observed by Dr. Vetch to follow the motion of the eye, and he says that they may, by this circumstance, be distinguished from those of the conjunctiva, "the vessels of the latter, independent of their *darker* colour, their more tortuous form, and varying size, have likewise a more longitudinal direction, and as they proceed from the angles of the orbit, they form radii of a larger circle. The distinction between the inflamed vessels of the conjunctiva and the sclerotica (says Dr. Vetch) I consider to be, therefore, obvious; but, *that any difference can be observed in the arrangement or appearance of the vessels of the latter, sufficiently distinct to indicate the peculiarity of the exciting cause or specific nature of the case, is more than I have been able to perceive.* The general character, as it arises out of the structure of the part, will be found the same, whether the cause be gout, rheumatism, or syphilis. The vessels, such as I have described them, will always be most observable on the upper portion of the eye, as it is in that place that the inflammation is most intense, except when its locality is affected by any external exciting cause, in which case it will be greatest near the injured part."—(*On Diseases of the Eye, p.* 29.)

While Dr. Vetch describes the vessels of the conjunctiva as exhibiting in sclerotic inflammation a darker colour than that of the vessels of the sclerotic coat itself, Mr. Travers represents the vessels of the *latter membrane*, which pursue a straight course to the margin of the cornea, as having a somewhat *darker hue than the areolar vessels upon the loose portion of the conjunctiva.*

It should be mentioned, however, that by sclerotic inflammation, Dr. Vetch signifies inflammation of the eye itself, as contrasted with conjunctival inflammation; but how far this will account for the differences above pointed out between his description and that of Mr. Travers, I am not prepared to say. According to Mr. Travers, ordinary inflammation of the sclerotica is secondary; that is to say, this membrane is usually affected only as intermediate to the conjunctiva and the other tunics. However, he has occasionally observed, in a recent ophthalmia, a turgescence of the vessels which pursue a straight course to the cornea, unaccompanied with any affection of the iris, and so slight a vascularity of the loose conjunctiva, that he was disposed to regard the case as a primary sclerotitis. The inflammation, he says, is not acute, and the motions of the eyeball are painful. It sometimes accompanies, and sometimes follows, rheumatic inflammation. If continued, it presents the vascular zone and a pupil contracted, or drawn a little to one side. It is often seen in company with eruptions or sore throat of a pseudo-syphilitic character, or is secondary to gonorrhœa.—(*Travers, Synopsis, &c. p.* 128.)

The practice recommended by this gentleman is as follows: obtuse pain in the eyeball, he says, may be materially relieved by blood-letting, and by antimony and ipecacuanha with opiates. Mercury is stated to have much less power over this case than iritis. In general, the patient is seriously reduced, and very irritable, from suffering rheumatic inflammation in the elbow, knee, or ankle; a state, to the production of which the previous use of mercury has commonly contributed. But though such is stated to be the case, the moderate and cautious employment of this mineral is set down as generally indispensable in the treatment. And, in the interval of the mercurial action, the nitric acid is alleged to be often of great service. The preparations of mercury preferred by Mr. Travers in these cases are the oxymuriate in doses of one-twelfth or one-eighth of a grain, and the hydrargyrus cum creta, in doses of from five to ten grains, twice or thrice a day As auxiliaries for allaying irritation, he prescribes the pulv. ipecac. comp., hemlock, hyoscyamus, and the extract of sarsaparilla, either dissolved in the decoction or taken solid.—(*Vol. cit. p.* 289.) On *rheumatic inflammation of the eye*, a few observations will be hereafter inserted.

Idiopathic Inflammation of the Internal Textures of the Eyeball, or Internal Ophthalmy in general. According to Beer, internal inflammation of the eye does not always originate in one particular texture, but, in some instances, commences in the retina, choroides, &c.; while, on other occasions, its principal seat is in the iris, from which membrane it quickly extends itself to the corpus ciliare, and the crystalline lens and its capsule, or else in another direction to the sclerotica, cornea, &c. These differences in the seat of the disorder obviously depend upon the way in which the exciting causes have operated; for, when they are such as immediately affect the retina only, the inflammation must have its origin in this texture, as when the disorder is produced by the effect of the sudden entrance of any very strong vivid or reflected light into the organ. This case Beer denominates *ophthalmitis interna idiopathica, proprie sic dicta.*

The exciting causes, however, may not affect directly the retina, and parts immediately next to it, but may operate chiefly upon the iris, in which event, this part is the chief seat of the inflammation, and the complaint is named, both by Schmidt and Beer, *iritis idiopathica.* This form of inflammation, Beer says, is seen after the extraction of the cataract, and accidental injuries of the eye, where the weapon with which they were produced has either penetrated directly to the iris, and more or less contused it, or roughly entered the eyeball near the ciliary edge of this membrane, without actually wounding it.—(*Lehre von den Augenkrankh. b.* 1, *p.* 421.)

Symptoms of the first stage of idiopathic internal

ophthalmy, properly so called. While a very uneasy sensation of general constriction and tension affects the whole eyeball, and soon changes into an obtuse, deep-throbbing pain, increasing every instant, and quickly propagating itself over the eyebrows to the top of the head, the power of vision gradually declines, and, at the same time, the pupil, which plainly loses its clear shining blackness, contracts, without being deprived of its circular figure, or drawn out of its natural position, until, at length, it is so completely closed, that the iris seems as if it had no aperture whatever. But long before this perfect closure of the pupil has taken place, the power of seeing is entirely gone, though, after the faculty of perceiving the external light is extinguished, fiery appearances, which seriously trouble the patient, are seen at each pulsation of the blood-vessels within the eye. As the developement of these symptoms is going on, the iris evidently loses its natural colour; becoming, as Beer says, greenish, when it it was gray or blue; and reddish, when it was brown or black. In consequence of the iris swelling, and projecting towards the cornea, the anterior chamber becomes considerably diminished. Immediately the least mark of the swelling of the iris is seen, together with a moderate degree of contraction of the pupil, the whole sclerotica assumes a pink-red colour; a plexus of innumerable blood-vessels is seen in the conjunctiva; and the cornea loses a good deal of its natural brilliancy, without being actually opaque. The latter symptoms of this form of ophthalmy are attended with manifest general indisposition, and intolerable headache. Sometimes, in the first stage of the case, the pupil, though much lessened, is not absolutely closed, but thickish, and, if examined with a magnifying glass, it has a reddish-gray appearance, and the power of vision, notwithstanding the continuance of the aperture, is quite lost.

Symptoms in the second stage. According to the same author, while the eye is suffering very irregular throbbing pain, attended with a sensation of heaviness and cold in it, an increase of the redness of the conjunctiva, severe constitutional disturbance, and constant shivering, there is suddenly formed at the bottom of the anterior chamber a collection of matter which above presents a horizontal line, but on every inclination of the head sidewise changes its position. This matter continues to accumulate more and more, until it not only reaches the pupil, but fills the whole of the anterior chamber, constituting the case termed *hypopium*. If the disease be left to itself, says Beer, the matter collects in such quantity, that the cornea is rendered more prominent, and afterward conical, very like an abscess, ultimately bursting during an aggravated attack of pain, when the eye shrinks, and the sufferings gradually cease. This kind of hypopium Beer names *true*, in order to distinguish it from the case in which the matter passes into the anterior chamber out of an abscess in the cornea, and which he terms a *false* hypopium. When, at the end of the first stage, the pupil is not entirely closed, one may discern in the second stage, at the period of matter presenting itself at the bottom of the anterior chamber (though not easily with the unassisted eye), whitish filaments, extending from the edge of that opening towards its centre, produced by the coagulable lymph effused in the aqueous humour, the secretion of which was interrupted in the first stage, but now commences again. And, continues Beer, one may perceive, with a good magnifying-glass, a very delicate cobweb-like membrane, which, when the matter collected lies over the pupil, and remains for a good while unabsorbed, at length becomes quite yellow, the matter being really encysted by it in the form of a small lump, which remains in the pupil, and partly projects into the anterior chamber, forming the case, which Beer denominates a *spurious purulent cataract*, to which the edge of the iris is so closely adherent, that sooner than a separation could be effected, the whole of the iris would be torn in pieces. When the pupil has been completely closed in the first stage, these effects of course cannot take place.

With respect to the causes of this form of ophthalmy, Beer remarks, that as there are not many circumstances which can produce it, the case belongs rather to the less frequent kinds of inflammation of the eye. As predisposing, he mentions plethora, and irritability of the eyes occasioned by little exercise of them. Experience has convinced him, however, that by far the most usual cause of this internal ophthalmy is an extraordinary, long-continued straining of the eye in the inspection of small microscopic objects in a strong reflected light.

Respecting the prognosis, he represents it as not unfavourable, when the inflammation of the eyeball is moderate, proper treatment immediately employed, the pupil not yet very much contracted, and the power of seeing not considerably impaired. But if the power of vision should seem as if it were abolished, the prognosis is extremely uncertain. And if the pupil should close after the entire stoppage of vision, no hope can be entertained of the recovery of the sight: for if the pupil open again on the subsidence of the inflammation, it will yet continue very small and motionless, and the eye blind. When the case is mistaken in its first stage, and neglected or erroneously treated, Beer says, it changes into a very perilous general inflammation of the whole eyeball; a disorder already considered.

In the second stage, the prognosis is constantly unfavourable; for the eyesight has always been already destroyed at the end of the first one, and the only expectation of the practitioner can now be to preserve the shape of the eye, while as speedy a check as possible is put to the suppuration. If the case has been so mismanaged in its first stage, that a violent inflammation of the whole eyeball is inevitable, and traces of chemosis are already present, the chances of the figure of the eye being lost in the second stage are still greater, and, as Beer observes, the surgeon will be fortunate, if he can now prevent a frightful morbid change of the organ.

In the treatment of the first stage, Beer describes the indications as being exactly the same as in common ophthalmy, except that no scarifications are necessary, unless the case change into a violent inflammation of the whole eyeball. However, great promptitude in the application of proper curative measures is here particularly called for, as the least delay is apt to cause either a total loss of sight, or at least a serious impairment of it.

With few exceptions, the treatment of the second stage is also like that of ophthalmy in general. Warm poultices, Beer says, can only be employed with great circumspection. When matter collects in the anterior chamber, he strongly condemns making an opening in the cornea, by which practice, he states, that the eye would certainly be rendered quite deformed. He recommends leaving every thing to the absorbents, the action of which is to be invigorated by general and local remedies. Poultices are now to be laid entirely aside, and the effect of warmth tried. Blisters are to be applied alternately behind the ear and on the temple. The eye is to be smeared with the vinous tincture of opium two or three times a day, by means of a camel-hair brush, or even four times, when the anterior chamber is filled to the extent of one-half of it. Beer's experience leads him to approve of opening the cornea only in very urgent cases, that is to say, when the eye is so distended with matter, that the cornea is in a state of an abscess, which threatens to burst. In one part of his observations, Beer describes the matter in these instances as fluid; a point on which he differs from Scarpa; but he afterward confesses, that when an opening is practised, the matter must not be expected to flow out immediately, like that of a common abscess.—(See *Hypopium.*)

Idiopathic Iritis. The following is Beer's description of the disease. Together with an obtuse, heavy, deep pain in the eye, producing a sensation as if the eyeball were continually pressed upon by one of the fingers, a manifest and incessantly-increasing uniform contraction of the pupil takes place, as well as a gradual diminution of the movements of the iris; yet the pupil neither loses its circular shape, nor changes its position in the eye, and, at the same time, an intolerance of light commences. When the pupil is examined with a glass, it is found to have already lost the shining blackness which is peculiar to it in the healthy state. While these changes are occurring in the pupil, the colour of the iris undergoes a material alteration, first at its lesser circle, which grows much darker, and afterward at its greater circle, which turns greenish when it was gray or blue, but reddish when it was brown or black. At the same time, the margin of the pupil becomes indistinct, and appears not so

sharp as natural. As soon as the greater ring of the iris has undergone a considerable change of colour, this membrane becomes evidently swelled, and projects towards the cornea, so that the anterior chamber is very much lessened. As early as the period when the contraction of the pupil and the immobility of the iris are observable, a serious diminution of the power of vision occurs; because, in all cases, the inflammation extends more or less over the anterior layer of the crystalline capsule, and afterward, when the case is somewhat more advanced, says Beer, one may perceive quite plainly, with the unassisted eye, those effects of inflammation on the capsule which have been so excellently described by Walther.—(*Abhandl. aus dem Gebiethe der Practischen Medicin*, *b.* 1, *Landshut*, 1810.) In proportion as the inflammation makes progress the pain grows more severe and extensive, and towards the end of the first stage it shoots particularly up to the top of the head; a circumstance strikingly proved whenever any thing like slight pressure aggravates the pain in the eye. The redness perceptible in the eye during the whole of the first stage is inconsiderable, and seems to be not at all proportioned to the violence and danger of the inflammation; for the sclerotica is only of a rose-red colour, and even this pale redness fades towards the circumference of the eyeball.—(*B.* 1, *p.* 434.)

According to Beer, idiopathic iritis is always attended with a corresponding general disturbance of the system; but a good deal depends upon whether the inflammation spreads immediately to the deeper textures of the eye, or to its outer coats, or in both directions at once. In the first case, the constitutional indisposition is always more severe, and the danger of the disease increases every moment; in the second instance, the augmentation of the general symptoms is less striking; but in the third, the inflammation, and the corresponding febrile symptoms soon rise in such a degree, that the possibility of preserving the eyesight becomes very doubtful. The continued operation of hidden exciting causes, neglect, and erroneous management of the disease, also produce considerable differences; and, as Beer observes, it not unfrequently happens, that a genuine idiopathic iritis, which does not appear at first very dangerous, nor rapid in its progress, will suddenly change, under the unfortunate concurrence of the circumstances above alluded to, into a complete inflammation of the whole eyeball, destroying the organ in a few days, unless the most efficient treatment be speedily adopted.

In the second stage, says Beer, in conjunction with a corresponding still more manifest general indisposition, the pain in the eye grows very irregular; luminous appearances flash within the organ and seriously annoy the patient, especially in the dark, while the power of seeing the external light undergoes a great decrease; the redness, even in the conjunctiva, increases; and the pupil, which hitherto has been perfectly circular, becomes more or less angular. At these angles, something of a light-grayish colour may be seen projecting behind the pupillary edge of the iris, and, on examination with a glass, plainly appears to be a very delicate layer of coagulating lymph, by which, first the lesser ring of the uvea, and (if proper treatment be not expeditiously employed) also its greater ring, are soon rendered adherent to the anterior portion of the capsule of the lens (*synechia posterior*), which membrane, as the disease advances, becomes more and more deprived of its transparency. Under these circumstances, it is evident that the power of vision must daily decline, and that if this process of the effusion of lymph and its organization be not resisted by powerful measures, the patient will soon be left just capable of faintly distinguishing the light. While the above-described changes are taking place between the uvea and anterior portion of the capsule, very peculiar effects are occurring in the anterior chamber: for as the iris continues to project farther towards the cornea, the latter membrane grows less and less transparent, and the iris seems as if concealed in a mist, at the same time that a small, yellowish-red, round prominence is formed at one or more places together, generally between the greater and lesser rings of the iris, and proves afterward to be a small abscess, which, ultimately bursting, pours its contents into the anterior chamber, and thus occasions a true *hypopium*. For several days, the flakes of the burst little cyst, still connected with the iris, may be seen floating in the aqueous humour, until they gradually disappear. When there is not merely one but several of these little abscesses, says Beer, the greater part of the anterior chamber may be filled with matter, so that little more of the iris can be distinguished. In weak subjects, at this period of suppuration, blood may not unfrequently be perceived in the chamber of the eye; a circumstance regarded by Beer as a very unfavourable omen in respect to the recovery of sight, as, in such cases, portions of blood and matter are apt to lie in the posterior chamber entangled in the lymph. According to the same author, the matter in the anterior chamber is at last absorbed; the pupil, if it has been concealed, can again be seen, but it appears angular and very turbid; and in consequence of the layer of lymph in the posterior chamber, the eyesight is exceedingly diminished, or even reduced to the mere power of knowing light from darkness. Such, says Beer, is the course of the second stage of idiopathic iritis, when the inflammation has not extended far beyond its proper focus, and has been principally confined to the iris, corpus ciliare, the lens and its capsule, and the anterior part of the sclerotica. But if it should spread more deeply to the vitreous humour, the retina, the membrana Ruyschiana, and the choroides, symptoms of internal ophthalmy (strictly so called) then occur with great vehemence in the first stage, and, at the termination of the second, the eyesight is for ever certainly destroyed in such a degree that not the least perception of light remains; and even if the patient should think that he can distinguish it, the feel is only a deception; a developement of light within the eye itself; of which the surgeon may easily assure himself, by placing the patient with his back towards the light, and asking him to point out where it is; or by putting him directly opposite a window, and moving the hand slowly along before his eyes; of which proceeding the patient will be quite unconscious. The effects left in the eye after such an iritis, and indicating its mischievous extension, are so characteristic, that on the first inspection of the eye no surgeon can entertain a doubt of the deeper textures of the eye having been involved in the inflammation. But when idiopathic iritis extends rather to the external than the deep textures of the eye, the swelled iris, as early as the end of the first stage, approaches so near the cornea, which grows less and less clear, that they seem as if they were adherent ere the second stage has commenced. And, indeed, on the accession of this stage, they actually adhere together at every point, either directly or with the intervention of a mass of coagulating lymph. In the first event, at the end of the second stage, the cornea forms a conical protuberance, and a total staphyloma arises (see *Staphyloma*); but in the second, the cornea is said not to undergo this change. On the contrary, it becomes rather flat, and on account of the layer of organized lymph which fills up the space between the cornea and iris, little of the latter membrane can be discerned, and what can be seen appears to have its organization entirely subverted. When idiopathic iritis in its first stage extends its effects directly over the whole eyeball, the eye becomes nearly or quite destroyed in the same manner as in cases of violent acute ophthalmy.

The causes which give rise to idiopathic iritis must always be such as operate directly upon the iris; and hence the disorder is usually a consequence of injuries and wounds of the eye, produced by accident or in operations. And, says Beer, although rheumatic inflammation of the eye, when neglected or wrongly treated, may at length affect the iris and adjacent textures, yet such an iritis is but a secondary effect, derived from the pre-existing rheumatic ophthalmy. All injuries in which the weapon or instrument has more or less pressed against, pushed, irritated, or violently bruised, or torn the iris itself, and all largish wounds of the cornea, are to be accounted the principal exciting causes of idiopathic iritis. Hence extraction of the cataract is not unfrequently followed by this inflammation, when the flap of the cornea is kept too long opened, and the iris is hurt with any blunt instrument; when the incision in the cornea is too small, and a hard cataract pushes the iris between the lips of the wound, and is slowly pressed out of the eye; when many pieces of the cataract break off, and it is necessary repeatedly to introduce Daniel's scoop for their

removal; or when, notwithstanding the operator proceeds with the utmost delicacy, the patient is excessively timid and unmanageable, or particularly irritable and prone to inflammation. This form of iritis is also produced by couching, reclination through the sclerotica, keratonyxis, and operations for artificial pupil. Nor, as Beer observes, is it at all surprising that iritis should follow these last operations, as the surgeon has often to meddle with an iris that has been already violently inflamed.

Prognosis in the first stage. Serious as the disorder always is, important as the textures are in which the inflammation is most severe, and quickly as vision may be for ever annihilated by it, yet, says Beer, the prognosis in the first stage is very favourable, when the true nature of the case is at once understood, and treated as it ought to be. The prognosis is the most favourable when the inflammation is not extensive; but it must be very reserved when the inflammation extends either deeply backwards, forwards, or in both directions. Beer remarks, that when iritis is purely idiopathic, and judiciously treated in its first stage, it is incredible with what rapidity its effects recede. When it is produced immediately by an injury of the iris itself, and some part of this membrane is torn, the risk of the inflammation is not the only thing for consideration; for the chance of the function of the iris being permanently impaired by the injury must also be taken into the account. And, says Beer, as in these severe injuries of the eyeball, it is impossible to foretel what may be the result of the inflammation, it is a good maxim always either to defer making any prognosis, or to deliver only a doubtful one. When idiopathic iritis has already changed either into a complete internal ophthalmy, or into a violent inflammation of the whole eyeball, no incautious promises should be made about the recovery of the eyesight, or even about preserving the shape of the eye.

Prognosis in the second stage. Though, says Beer, this is much less favourable than in the first stage, yet, if proper measures be not deferred, a perfect recovery of the eye may often be effected. Here a great deal depends upon the state of the layer of lymph effused in the posterior chamber, and of suppuration. If it be plain to the naked eye, that no coagulating lymph lies in that chamber behind the contracted pupil, but slight grayish filaments are discernible with a magnifying-glass, projecting only a little way from behind the pupillary edge of the iris; if the colour merely of the lesser circle of the iris be changed, while no little cyst of matter is yet formed on the latter membrane, and the sight is lessened only in a small degree, being somewhat cloudy; the complaint may be so completely cured by proper means, that not a vestige of it will remain. However, for some time after the termination of the second stage, the motions of the iris will be more sluggish than natural, though the pupil effectually adapt itself to the variations of light. On the other hand, when a considerable, though fine, web-like membrane can be plainly seen behind the pupil; when the colour of the larger circle of the iris is somewhat altered; and the power of vision is seriously lessened; though, by effectual treatment, the sight may be re-established sufficiently to enable the patient to read and write; yet, says Beer, it will for ever continue weak; the pupillary edge of the iris will never regain its perfect freedom, but constantly remain more or less angular, and the pupil never assume again the clear shining blackness, which, in persons not of great age, it naturally exhibits. Still more remarkable are the sequelæ of idiopathic iritis, when a small cyst of matter has been formed on the iris, and discharged its contents into the anterior chamber; for, in this case, under the best circumstances, the former colour of the iris never entirely returns. According to Beer, when at the first visit of the surgeon, vision is quite interrupted by the effusion of lymph in the posterior chamber, so that the patient can no longer perceive any object with the affected eye, though capable of distinguishing the light, and the outlines of some things; when the pupil is at the same time very contracted, and the colour of the greater circle of the iris entirely changed: there is no hope of recovery of the sight at first, though some chance of benefit may be subsequently afforded by the formation of an artificial pupil. If, says Beer, in such a case, matter has been effused, from several little suppurating points of the iris, so copiously into the anterior chamber, that nearly all this cavity, or at least the half of it, is filled up, though after absorption some power of distinguishing light may return, little or no hope can be entertained of any effectual benefit from a future operation for an artificial pupil. When, at the termination of the first stage, the cornea is so severely inflamed, that the iris almost touches this membrane in its untransparent thickened state, all prospect of saving the eyesight is over, and it will be fortunate if the natural shape of the eye can now be preserved, and the formation of a staphyloma of the cornea prevented. When the layer of lymph between the cornea and the iris is extensive, and considerable blood-vessels can be seen proceeding into it from the iris, Beer says, nothing will succeed in re-establishing vision. And he observes, that when an idiopathic iritis, at the close of its first stage, has changed into a true internal ophthalmy, and the pupil is already quite blocked up, so that even the light cannot be distinguished, the recovery of sight is quite impossible, and the surgeon must make every exertion to prevent the shape of the organ from being destroyed. In this disease, says Beer, a relapse, even when the inflammation has not been very considerable in the first attack, almost constantly ends in partial or complete blindness of the affected eye, as the progress of the case is so rapid that there is not time enough to render effectual assistance.

Beer directs idiopathic iritis to be treated in its first stage like a case of pure internal ophthalmy, the practice being somewhat modified, however, according to the direction and degree in which the inflammation has spread, when the surgeon is first consulted. When the inflammation continues a good while limited, or spreads but very gradually to the outer texture of the eyeball, general and local antiphlogistic remedies are to be employed with moderation; but if it immediately extend itself to the innermost parts of the eye, or both inwards and outwards together, and threatens to end in a universal inflammation of the eyeball, antiphlogistic treatment must be most rigorously adopted.—(*Beer.*) This author then notices the unfortunate state of the case, when, towards the end of the first stage, the eyesight happens to be entirely destroyed, the iris is close to the cornea, and there is danger of a staphyloma. In this desperate state of things, his apprehensions of this last disease lead him to suggest a plan (the propriety of which I regard with much suspicion), which is nothing less than actually trying to increase the inflammation, by stimulating the eye several times a day with laudanum, sulphuric ether, &c. with a view of doing what? Why, of obliterating the sources of the aqueous humour! the continuance of the secretion of which is set down as one of the essentials to the production of staphyloma.—(*B.* 1, *p.* 447.)

The treatment of idiopathic iritis in its second stage, as recommended by Beer, is, on the whole, both generally and locally, like what has been advised for the same stage of pure internal ophthalmy; but here, he says, it is necessary to pay particular attention to the direction in which the inflammation extends itself in the first stage, so that the treatment may be regulated with greater precision. Beer also advises great attention to be paid to the effusion of lymph in the posterior chamber; as, towards the end of the second stage, much may be done which would afterward be too late. Thus, when the surgeon perceives, towards the end of the second stage, that the layer of lymph in the posterior chamber does not completely prevent, though it seriously diminishes vision, and that it is likely to remain in the same state after the termination of the second stage, Beer recommends topical applications to the eye, and, if these prove unavailing, internal alterative medicines, and even mercury, which, he says, when the treatment is judiciously conducted, ought not to be omitted. Here, also, he observes, another deviation must be made from the usual practice in the second stage of ophthalmy: calomel joined with opium, is to be exhibited with calamus aromaticus, bark, &c. Externally, Beer speaks highly of the benefit of a collyrium, containing the oxymuriate of mercury, without any mucilage, but with a considerable addition of the vinous tincture of opium. When these remedies cease to be efficacious, or the eye cannot bear fluid applications, as is sometimes the case, Beer recommends a bit of the following salve to be smeared once a day between the edges of the eyelids, and allowed slowly to melt there, and become diffused over the eye: R. Bu-

tyri recentis insulsi ʒij. Hydrargyri nitrico-oxydi rubri gr. vj. Extract. opii gr. viij. M. Beer also states, that rubbing a little mercurial ointment, with which some opium is blended, once a day into the eyebrow, will greatly promote the removal of the lymph effused in the posterior chamber.—(*B.* 1, *p.* 450.)

Excellent as Beer's description of idiopathic iritis certainly is, there are some imperfections in his method of treatment. 1st, It does not appear to me, that he insists sufficiently upon the necessity of taking away a very large quantity of blood at the commencement of the case, and of repeating the general and topical bleeding, until the circulation is duly lowered, and the violence of the inflammation checked. 2dly, Though his recommendation of rigorous antiphlogistic treatment implies the approbation both of bleeding and cathartics, he says nothing of the use of moderate doses of tartarized antimony, in weakening the pulse, a practice highly praised by the late Mr. Saunders.—(*On Diseases of the Eye*, *p.* 26, 8*vo.* 1811.) 3dly, If mercury has the power of arresting acute inflammation of the iris, "both prior to and after the effusion of adhesive matter," and of rapidly removing, "by an excitement of the absorbing system, peculiar to itself, the newly-effused matter" (*Travers*, *Synopsis*, *&c. p.* 291), then Beer must delay too long the employment of this powerful medicine, since he does not commence its use until the close of the second stage, when he has found that the absorption of the effused lymph cannot be effected by other means. 4thly, Beer entirely overlooks the important utility of belladonna and hyoscyamus in producing a dilatation of the pupil, whereby adhesions of the iris to the capsule of the lens, or to the cornea itself, may frequently be prevented, or their ill effects considerably lessened. Belladonna (says Mr. Saunders), "if properly applied to the eye, during the adhesive process of inflammation, will cause the inner margin of the iris to expand and recede from the axis of the pupil, and will thus overcome the restraint arising from the agglutination of lymph, by elongating the organized bands which connect the iris and capsule, if they have not been of long duration. Thus, the adhesions are drawn out to a degree of tenuity, and consequently transparency, and a considerable quantity of light is admitted. If the effect of the inflammation has been slight, the adhesions will be trivial, and the pupil only slightly irregular. The iris will retain a certain power of action, and vision will be very little injured. In general, the pupil is misshapen, and the iris perfectly fixed; but if the aperture be of sufficient size, and the capsule not rendered too opaque, the patient will enjoy a very useful degree of sight."—(*Saunders*, *p.* 32.) Respecting belladonna, it is observed by Langenbeck, that, as all applications directly to the inflamed eye itself are frequently hurtful, and render it still more painful and irritable, it is a good plan to let the extract of belladonna be smeared upon the eyebrow, instead of puting a solution of it immediately in contact with the conjunctiva.—(*Neue Bibl. b.* 2, *p.* 236.) The same author expresses his attachment to Beer's method of rubbing mercurial ointment with opium into the eyebrows; and after dwelling, with due force, on the necessity of copious and repeated bleedings, leeches, evacuations, &c. he cautions practitioners not to be led into the supposition, that the efficacy of belladonna will supersede the occasion for taking away blood. He even declares, that, during the first vehemence of the inflammation, the application is quite inefficient, and that it frequently will not succeed in producing a dilatation of the pupil, before bleeding has been practised. "If (says Langenbeck) bleeding is to be useful in iritis, it must be copious, and often repeated."

Specific Cases of Iritis. The foregoing observations refer to idiopathic iritis, or inflammation of the iris uncomplicated with any specific disease. But there is an iritis, which "appears in company with rheumatism of the chronic form; sometimes with gout; with the constitutional signs of the lues venerea; and during or following the action of mercury upon the system."—(*Travers*, *Surgical Essays*, *part* 1, *p.* 59.)

Mr. Hunter entertains doubts whether any inflammations of the eyes are syphilitic, and he appears to found his opinion upon two circumstances: one is, that if such cases be venereal, the disease is very different from what it is when it attacks other parts, and is attended with more pain than venereal inflammation arising from an affection of the constitution: the second is, that he never saw these cases attended with such ulceration as occurs when the complaint invades the mouth, throat, and tongue.—(*Hunter on the Venereal Disease*, *p.* 324.) On the other hand, the generality of modern surgeons believe in the reality of venereal ophthalmy, though their accounts of the symptoms and appearances of the complaint are in some respects discordant. Scarpa says, the venereal ophthalmy is peculiar in not discovering manifest signs of inflammation, stealing on clandestinely, *without much uneasiness*. It afterward relaxes the vessels of the conjunctiva and lining of the palpebræ, and changes the secretion of Meibomius's glands. In time, it causes ulceration of the margins of the eyelids; the ciliæ fall off, and the cornea grows opaque. In the worst stage it excites itching in the eyes, which is exasperated at night, and abates in violence towards morning, as do almost all the effects of syphilis. It never attains the state of chemosis. With the exception of the venereal ophthalmy in the form of iritis, I cannot discover that any thing very certain has yet been made out. By this observation, however, it is not meant to assert, that cases corresponding to Scarpa's description do not present themselves, and may not be relieved by his method of treatment; but that their venereal character is not fairly proved. In examples like those described by Scarpa, the decoct. sarsap., the oxymuriate of mercury, mezereon, guaiacum, and even mercurial frictions, may be employed with leeches and blisters. Scarpa particularly recommends a collyrium made with the oxymuriate of mercury. When the eyelids are ulcerated, the unguentum hydrargyri nitrati, weakened at first with twice or thrice its quantity of the unguentum cetaceum, is the best topical application

The iris is now supposed to be more liable than any other part of the eye to venereal inflammation.—(*Wardrop's Essays on the Morbid Anat. of the Eye vol.* 2, *p.* 36.) The case is mentioned by Mr. Saunders who recommends the vigorous exhibition of mercury and the use of belladonna. Its symptoms and treatment, however, have been more particularly detailed by Beer.—(*Lehre von den Augenkr. b.* 1, *p.* 553.) As this case and some other specific forms of iritis are described in the two last editions of the First Lines of Surgery, I need here only refer the reader to that publication, and to a few works containing additional information on iritis in general; as *Saunders's Treatis on some Practical Points, relating to Diseases of the Eye*, *p.* 21, 8*vo.* 1811; *and particularly the later editions, in which the utility of mercurials is noticed.*

In the article *Hypopium* I have referred to an early case, in which the quick exhibition of mercury and its good effects were exemplified in Germany. But whatever claims the continental surgeons may have respecting the first administration of mercury in iritis, I believe it a justice due to Dr. Farre and Mr. Travers to state, that these gentlemen have undoubtedly given, not only the best practical directions on the subject, but laid the greatest stress upon the necessity of the practice, establishing the efficacy of mercury, as a means *as well of resisting the effusion of lymph* in the eye as of exciting the absorption of it after it has been effused. —(See *Travers*, *in Surgical Essays*, *part* 1.) Consult also *J. Vetch*, *A Practical Treatise on the Diseases of the Eye*, *p.* 88, *&c.* 8*vo. Lond.* 1820. *Weller's Manual of the Diseases of the Human Eye, transl. by Monteath*, 8*vo. Frick on Diseases of the Eye*, *p.* 65, *&c. ed.* 2, *with notes by Welbank* 8*vo. Lond.* 1826.

Rheumatic Inflammation of the Eye. According to Mr. Wardrop, the albuginea acquires a brick-red tinge or an admixture of yellow with crimson red, which colour, he supposes, is probably caused by the serous part of the blood being tinged with bile; "an effect likely to take place from the marked derangement of the biliary organs which usually accompanies this disease." Contrary to the statement of Beer, who describes the blood-vessels as being in clusters, Mr. Wardrop observes, that they are generally equally numerous over the whole white of the eye, passing for

wards in nearly straight lines from the posterior part of the eyeball, and advancing close to the cornea; but neither passing over it, nor leaving the pale circle around it, which is so striking when either the choroid coat or the iris is inflamed. If the vessels be closely examined, the general redness will be found produced more by numerous small ramifications than a few large trunks. There is frequently a little swelling of the conjunctiva which sometimes forms a slightly elevated ring round the cornea. In mild cases, little change takes place in the anterior chamber in the early stage; but as the disease advances, the cornea becomes dull and turbid. Upon close examination, one or more of the layers of the conjunctiva on the cornea will generally be found to be abraded, especially towards its circumference. At the commencement of the disease there is often a disagreeable feeling of dryness of the eye; but sooner or later a very copious secretion of tears takes place. The eyelids are observed to be very little affected. At first, the chief seat of pain is generally in the head, though sometimes in the eyeball itself. Mr. Wardrop describes the pain as usually most severe in the temple of the affected side, but he says that it is often seated in the brow, the cheek-bone, the teeth, or the lower jaw. "Sometimes the pain is precisely confined to one-half of the head, and sometimes there is a severe pain in the cavity of the nose or in the ear. The pains are more of a dull agonizing kind than acute, and, though unceasing, they vary much in degree, coming on at times in very severe paroxysms, and with great violence when the head is bent downwards. Sometimes the pain is excited by merely touching the scalp, and the patient is unable to rest his head on the affected side or even lean it on a pillow. In most cases the pain is said to be remittent, the paroxysm coming on in the evening, continuing during the night, being most severe about midnight, and abating towards morning.

In the eyeball, says Mr. Wardrop, the patient generally complains more of a sense of fulness and distention than of pain; and though there is a great degree of external redness, *the eye does not seem to suffer from exposure to light*; a point on which Professor Beer delivers a directly opposite statement, at least, in relation to the first stage of the disease. However, these authors both agree in considering the sclerotica as generally the chief seat of rheumatic inflammation; but Beer sets down the iris as likewise subject to be attacked. He admits also, that, in the second stage, the aversion to light undergoes a considerable diminution. According to Mr. Wardrop, rheumatic ophthalmy is always accompanied with more or less symptomatic fever, severe paroxysms of which take place towards evening, and the functions of the primæ viæ are much deranged, "the appetite being impaired, and the evacuation always changed in quality." In severe cases, the pain in the head soon becomes agonizing, the redness of the eyeball increases, the whole white of the eye is crowded with blood-vessels, and the conjunctiva swelled. At length ulceration commences in the cornea, through which the aqueous humour is discharged, and the eyeball collapses, when all pain ceases; or abscesses may form within the posterior chamber and burst through the sclerotic coat.—(*Wardrop, in Med. Chir. Trans. vol.* 10.) Beer describes small watery vesicles as forming on the cornea or white of the eye, and changing during severe pains into small ulcers, which occasion an appearance, as if a small piece were torn out of the surface of the cornea. He adds, that they seldom leave scars behind; but generally little pits, which are soon filled up in healthy subjects.—(See *Weller on Diseases of the Eye, vol.* 2, *p.* 217.)

The causes of rheumatic ophthalmy enumerated by writers are, change of weather, variation of temperature, exposure to damp, a cold current of air directly striking the eye, and a constitution disposed to rheumatism. Mr. Wardrop states, that both sexes are equally subject to the disease; but that he has observed it most frequently in adults, and persons of rather advanced age. Only one eye is usually affected; and when the second is attacked, the disease is almost always less severe in it than that which is first inflamed.

According to Mr. Wardrop, rheumatic ophthalmy resembles syphilitic more than any other kind of inflammation of the eye. But he notices, that *in rheumatic ophthalmy the proper vessels of the sclerotic coat are enlarged*, which is the cause of the redness being generally diffused over the whole albuginea, whereas, *in syphilitic inflammation it is the anterior ciliary arteries passing along the sclerotica on their way to the iris, which are chiefly affected;* and hence the pale ring which is always observed between the cornea and the enlarged vessels. Mr. Wardrop farther explains, that though these diseases resemble each other in the pains round the orbit and their evening exacerbation, *patients with syphilitic ophthalmy always have the constitutional symptoms of syphilis.*

When the disease has made much progress, and the symptoms have not yet yielded to other remedies, Mr. Wardrop recommends the evacuation of the aqueous humour, as a practice from which the most beneficial effects may be expected. After the operation, fomentations are the only necessary applications; but if the eye continue long irritable, the vinous tincture of opium is to be used. He enjoins attention to the state of the biliary organs in every stage of the disease, and speaks highly of the sudden relief sometimes afforded by an emetic, care being taken to empty the bowels afterward with calomel and rhubarb, or other purgatives. If the functions of the skin were suddenly interrupted by a chill just before the attack, this author prescribes a couple of grains of antimonial powder, alone, or combined with opium, to be taken every four or six hours. Little advantage, he says, is derived from local bleeding, and where venesection may become necessary on account of the complaint resisting other means, it is to be practised with moderation.

In the early stage, Mr. Wardrop has found, that the pain in the eye and eyebrow is sometimes much alleviated by a fomentation with the decoction of poppy-heads. He also praises blisters to the nape of the neck or behind the ear; but disapproves of their being put near the eye itself. The vinous tincture of opium, he says, is the only local application which he has ever seen decidedly beneficial; but its use is to be deferred till a late stage of the inflammation, when all febrile symptoms have been subdued. "After the primæ viæ have been well evacuated, the tongue may still remain very white, and the pulse quicker than natural." In this state, small doses of bark, either alone or with the mineral acids, will be most serviceable.—(*Wardrop, in Med. Chir. Trans. vol.* 10.) The outlines of Beer's practice may be given very briefly: in the first stage, he applies a leech to the inner canthus, and covers the eye with a cold poultice, with a small proportion of vinegar in the water with which it is made. Diaphoretics are also prescribed. In the second stage, guaiacum, camphor, arnica, antimonials, blisters to the neck, or behind the ears, frictions with opium over the eyebrows, and covering the eyes with bags of aromatic herbs and camphor, are the means of relief. When abrasions or ulcerations exist on the conjunctiva, sclerotica, or cornea, a collyrium of the lapis divinus, with a large addition of the vinous tincture of opium, is commended; or if the ulcers are large, and on the cornea itself, they may be touched with the latter tincture by means of a camel-hair pencil. After each use of the collyrium, Beer covers the eye again with the bags of aromatic herbs and camphor.—(See *Weller on Diseases of the Eye, vol.* 2, *p.* 218.) Respecting the last application, I have already expressed my belief, that it is one which is not likely to obtain credit among English surgeons.

Scrofulous Ophthalmy. One of the peculiarities of this case is, that it is not attended with pain. As Dr. Frick observes, the same fact is remarked with respect to scrofulous inflammation in other parts: it is every where characterized by a dulness of sensibility.—(*On Dis. of the Eye, p.* 33, *ed.* 2.) According to Mr. Travers, when strumous inflammation of the conjunctiva has not proceeded to change of texture, it is not marked by any prominent local character. "The vascularity is inconsiderable. This inflammation sometimes accompanies pustule of the sclerotic conjunctiva, in which case the vascularity is diffused, instead of being partial as in pure pustular inflammation, and the *intolerance of light characteristic of the strumous inflammation* is present in a greater or less degree. It accompanies also the morbid secretion of the lids when the eyeball becomes affected by the acuteness and duration of that disease, and the pustule on the cornea, especially the variolous pustule. In its simplest form, it is almost peculiar to young children, ste-

tionary, marked by a very slight redness of the sclerotic conjunctiva, and the greatest possible degree of intolerance (*of light*)." The same author attributes the disease to a morbid sympathy of the retina with the secreting surfaces of the primæ viæ and skin. The following is the treatment proposed by Mr. Travers, for each form of scrofulous ophthalmy:

1. *Strumous inflammation without change of texture, vascularity more or less, intolerance* (of light) *excessive.* Calomel and opium at night; emetic tartar to continued nausea; gentle alvine evacuants; diaphoretic drinks; large open blister on the nape of the neck; leeches; tepid bath; tepid or cold water washes as most agreeable; vapour of opium; large bonnet shade; no bandages; spacious airy apartments; and light bed-clothing.

2. *With recent diffused opacity of the corneal conjunctiva, and vessels raised upon and over-shooting the corneal margin.* Calomel and opium to slight ptyalism; purgatives on alternate days; leeches; blisters alternated behind the ears and on the nape of the neck and temples. As the acute stage passes off, repeated circular sections of the vessels on the sclerotica, near the margin of the cornea.

3. *With herpetic ulcers of the cornea.* The same; blisters on the temples: as the inflammation yields, solut. argent. nitrat.; vin. opii; solut. cupr. sulph.; dilute zinc lotion.

4. *With pustules.* If partial, weak zinc, or alum lotion; ung. hydrarg. nitrat.; occasional brisk purgatives; infusion of roses with additional acids; tonic bitters; columba; gentian, &c.; blisters behind the ears, repeated if necessary: if the vascularity is diffused by the multiplication of pustules or the duration of inflammation, with irritability to light, treatment as in strumous inflammation without breach. Ung. subacet. plumbi.

5. *With inflammation of the follicles and puriform discharge.* Active measures at first, but not long continued. Blisters; when becoming chronic, with thickened lids, scarifications; zinc, alum, or copper wash, dilute; ung. hydr. nitrat.; hydr. nitr. oxyd.; subacet. cupri; tonics and sedatives: if obstinate, issue or seton.

6. *Convalescent state.* Infusion of roses; cascarilla; columba; decoction of bark, with dilute sulphuric or nitric acid; steel, rhubarb, and soda; or magnesia, as aperients; tonic collyria and gently stimulant ointments; nutritive diet; country air; shower or sea-bath in the warm months.—(*Travers's Synopsis, &c. p.* 92—260, *&c.*)

When I look at the discordant accounts of what are called scrofulous affections of the eye, and the difference of practice laid down by different writers, I leave the subject with an impression that the terms *scrofulous* and *strumous* are here employed as much at random as in any other cases which can be specified. Indeed, the attempt to reconcile the various statements and descriptions of scrofulous ophthalmy, would puzzle the most able man in the profession; and it is with this belief, that I avoid contrasting the sentiments of Beer, Weller, Lloyd, Frick, and other modern writers, with those already delivered.—(See particularly *Beer's Lehre von den Augenkr. b.* 1, *p.* 588, *&c.*; *Weller's Manual of the Diseases of the Eye, vol.* 2, *p.* 265, *&c.*; *Lloyd on Scrofula, p.* 312; *and Frick on the Eye, ed.* 2.)

Chronic Ophthalmy. Unfavourable peculiarities are met with in practice, which prevent the complete cure of the second stage of acute ophthalmy, or that connected with a weak vascular action in the part affected; whence the protracted disease becomes purely chronic, and threatens the slow destruction of the eye.

These peculiarities may be chiefly referred to three causes: 1. To an increased irritability continuing in the eye after the cessation of acute inflammation. 2. To some other existing affection of the eye or neighbouring parts, of which the chronic ophthalmy is only an effect. 3. To constitutional disease.

1. That chronic ophthalmy may depend upon a morbid irritability of the eye is evinced, not only from its resisting topical astringents and corroborants, to which the disease from simple relaxation and weakness yields, but from its being exasperated by them, and even by cold water. The patient complains of a sense of weight in the upper eyelid, and restraint in opening it; the conjunctiva has a yellowish cast, and when exposed to the damp cold air, or a brilliant light, or when the patient studies by candle-light, its vessels become injected and turgid with blood. If, in combination with such symptoms, the habit of body be weak and irritable; subject to spasms, hypochondriasis, &c.; then it is manifest, that the chronic ophthalmy is connected with a general impairment of the nervous system.

2. Besides extraneous bodies lodged between the palpebræ and eyeball, the inversion of the ciliæ, and hairs growing from the caruncula lachrymalis; ulcers of the cornea; prolapsus of the iris; herpetic ulcerations of the margins of the eyelids; a morbid secretion from the Meibomian glands; a diseased enlargement of the cornea, or of the whole globe of the eye, &c., may occasion and maintain chronic ophthalmy.—It is only my part here to mention such remote causes; for the particular treatment of them is described in other articles.—(See *Cornea, Ulcers of; Iris, Prolapsus of; Lippitudo; Staphyloma; Hydrophthalmia. Trichiasis, &c.*)

3. The cure of the second stage of acute ophthalmy may be retarded by the prevalence of scrofula in the system, or by small-pox affecting the eyes. According to Scarpa, chronic ophthalmy is also sometimes a consequence of lues venerea; but I know nothing certain on this subject in addition to what has been stated in the foregoing columns.

When chronic ophthalmy depends upon preternatural irritability, the internal exhibition of bark with valerian is proper; animal food of easy digestion; gelatinous and farinaceous broths; wine in moderation; gentle exercise; living in salubrious and mild situations; are all severally productive of benefit. Externally, the applications should be of the sedative and corroborant kind; such as aromatic spirituous vapours (from the *spiritus ammon. comp.*) applied to the eye through a funnel for half an hour, three or four times a day; and the eyelids and eyebrows may also be rubbed with the linimentum camphoræ.

Patients, both during the treatment and after the cure, must refrain from straining the eye, and immediately the least uneasiness is felt, must desist from exercising it. When they write or read, it should constantly be in a steady, uniform light; and too little, as well as too much exercise of the organ, aggravates the disease. Having once begun to use spectacles, they should never study, nor survey minute objects without them.—(*Scarpa.*)

Intermittent Ophthalmy. It is the character of certain forms of ophthalmy, like the rheumatic and venereal, to be liable to periodical exacerbations; but I am not certain that there are any cases specifically claiming the name of *intermittent ophthalmy.* The late Mr. Ware, however, has noticed some examples which intermitted, or at least remitted, at stated periods. In these, he did not find bark so useful as in scrofulous ophthalmy; but he had seen the most beneficial effects produced by the oxymuriate of mercury, sometimes joined with the compound decoction of sarsaparilla.

Variolous Ophthalmy. As the small-pox inoculation has at present almost generally been abandoned by the faculty in favour of the vaccine disease, there seems less occasion now for detailing circumstantially a very obstinate species of ophthalmy, induced by the former complaint. When the small-pox eruption is very abundant in the face, it causes a considerable swelling of this part of the body; the eyelids become tumefied, the eyes redden, and there ensues a discharge of a very thick adhesive matter, which agglutinates the palpebræ together; so that, if no steps be taken, the eyes will continue closed for several days in succession. The matter confined between the eyelids and globe of the eye, being perhaps of an irritating quality, and injurious from the pressure it occasions on the surrounding parts, seems capable of exciting ulceration of the cornea, and even of irremediably destroying vision. When the pustules of the small-pox in other parts of the body have suppurated, they cicatrize; but those which happen within the margin of the cartilage of the eyelids are prevented from healing by the diseased secretion, which is then made from the Meibomian glands, and such ulcers result, as will sometimes last for several years, and even during life, if unremedied by art.—(*St. Yves sur les Mal. des Yeux, p.* 216, *edit.* 12*mo.*) After the employment of the antiphlogistic treatment, should the disease, when treated with topi-

cal astringents and corroborants, yet baffle the efforts of the surgeon, setons in the nape of the neck, kept open for a long while, prove one of the most useful remedies. Scarpa has experienced much advantage from giving, every morning and evening, to a child ten years old, a pill containing one grain of calomel, one grain of the sulph. aur. antim. and four grains of cicuta in powder. It is obvious, that so potent an alterative, if ever serviceable in this case, will soon evince its efficacy; nor would it be justifiable to sport with the patient's constitution by continuing its use beyond a certain period, unless sanctioned by evident signs of its salutary effects on the disease of the eyes.

When great irritability prevails, a mixture of three drachms of the vinum antimoniale, and one drachm of the tinctura thebaica, given in doses of five or six drops, in any convenient vehicle, and, at the same time, applying externally the vapours of the spiritus ammon. comp. to the eye, constitute an excellent plan of treatment. In other cases, saturnine collyria, with a little camphorated spirit of wine or white wine, in which a little sugar is dissolved; tinct. thebaica; Janin's ointment, &c. avail most. This treatment is also applicable to the chronic ophthalmy from measles.

When inveterate ulcers remain upon the edges of the palpebræ, the disease may then be regarded as the psorophthalmy, described by Mr. Ware, and will demand the same method of cure.—(See *Psorophthalmy.*)

Operation of discharging the aqueous humour. To this practice, some allusion has been already made in the preceding columns; and as the proposal is intended to apply to several forms of inflammation of the eye, I have not given any particular account of it in treating of the various cases. Mr. Wardrop remarked, that if the eye of a sheep or ox be squeezed in the hand, the whole cornea instantly becomes cloudy, and whenever the pressure is removed, this membrane completely regains its transparency.—From this curious phenomenon in the dead eye, it was evident that in the living body the transparency of the cornea might vary according to the degree of its distention; and that, in cases of opacity of the cornea, accompanied with fulness of the eyeball, its transparency might be restored by the evacuation of the aqueous humour. The cornea is little sensible, and, as every body knows, its wounds are free from danger. Mr. Wardrop soon met with a case favourable for making the experiment: the cornea was milky and opaque, and the eyeball distended and prominent, attended with acute inflammatory symptoms. The aqueous humour was discharged by a small incision, and the operation produced not only a removal of the cloudiness of the cornea, but an abatement of the pain, and a sudden check to all the inflammatory symptoms. From the success of this case, Mr. Wardrop was led to perform the operation on others, not only with a view of diminishing the opacity of the cornea, but also of alleviating the inflammation. Four interesting cases are related by this gentleman, very much in favour of the practice when the eye is severely inflamed, attended with fulness of the organ, a cloudy state of the cornea, and a turbidness of the aqueous humour. Mr. Wardrop also advises the operation whenever there is the smallest quantity of pus in the anterior chamber, accompanied with violent symptoms of inflammation. He thinks that the great and immediate relief which the method affords, is imputable to the sudden removal of tension; and he performs the operation with a small knife, such as is used for extracting the cataract. The instrument is to be oiled, and introduced so as to make a wound of its own breadth, at the usual place of making an incision in the extraction of the cataract. By turning the blade a little on its axis, the aqueous humour flows out.—(See *Edinb. Med. Surg. Journal, Jan.* 1807; *also Med. Chir. Trans. vol.* 4.) Mr. Lawrence has tried this plan in some instances; but his opinion of it is by no means favourable; for he says, that so little benefit resulted from it, that he has not been induced to persist in the practice; and he has been the less inclined to do so in severe inflammations of the eye, because they are completely controlled by ordinary antiphlogistic means. [Professor Sewall, of Columbian College, D. C., a distinguished practitioner of Washington City, has obtained extensive reputation by his success in the treatment of ophthalmia, and particularly the purulent form of this disease. By a communication with which he has recently favoured me, I learn that after a previous course of depletion, which he pursues with great energy, in all cases of ophthalmia, he relies chiefly upon *pressure* in almost every form of the disease, and especially

in the purulent kind. So soon as the active symptoms are subdued by the antiphlogistic regimen, he applies over the eye a pad of silk or soft linen, then a bat of carded cotton, or scraped lint, which he confines by a thin light bandage so tight as to afford gentle and comfortable compression to the eye, so as not to produce pain or uneasiness, however, by its intensity. This compress he removes twice in the twenty-four hours, and replaces it immediately by another of similar material. By this course he thinks he fulfils three indications, viz:

1st. Effectually to exclude the light from the eye;

2d. The globe of the eye is prevented from rolling; and,

3d. The distended vessels are compressed and disgorged.

His observation has detected, in most cases of ophthalmy, that there is a portion of the globe of the eye in which the vessels are more turgid than elsewhere, and this is in a line extending from the inner and outer canthus of the eye and corresponds to the triangular groove formed by the lids when closed; and arises, as he conceives, from a want of pressure from the lids of the eye.

This practice was, I believe, originally proposed and adopted by Dr. Francis Moore, of Massachusetts, a gentleman of high reputation both as a physician and surgeon. Professor Sewall, however, has for sixteen years tested its utility, and recommends it to his class with great confidence. From the few trials I have seen of this method, I am inclined to judge favourably of its merits.

During the time he is using compression, a minute quantity of a cerate is introduced into the eye, to which Dr. S. attributes great virtues in almost every violent form of the disease. It is prepared in the following manner, viz:

℞. Hydarg. oxyd. rub. grs. xlv.; lapis calaminaris, grs. xxx.; cinnabar native, grs. xv.; litharge, grs. xxx.; axungia porc. oz. j.; levigate separately and mix.

This cerate may, of course, be diluted with lard to adapt it to milder cases of the disease, if it should be thought too active.—*Reese.*]

OSCHEOCELE. (From ὄσχεον, the scrotum, and κήλη, a tumour.) A hernia which has descended into the scrotum.

OSTEOSARCOMA, or Osteosarcosis. (From ὀστέον, a bone, and σάρξ, flesh.) This term signifies the change of a bone into a substance of the consistence of flesh, or rather the growth of a fleshy, medullary, or cartilaginous mass within the bone, whereby at first an enlargement of the original bony cylinder or shell is produced, and at length its partial absorption, and sometimes fracture. Bones are sometimes converted into a substance, resembling that of a cancerous gland; and it is this affection to which Boyer thinks that the appellation ought to be confined.

Callisen seems also to regard the osteosarcosis as a disorder by which the texture of the bones is converted into a fleshy or fatty substance, accompanied with a tendency to carcinoma.—(*System. Chirurgiæ Hodiernæ, p.* 204, *vol.* 2. *edit.* 1800.) We are to understand by osteosarcoma, says Boyer, an alteration of the osseous structure, in which, after more or less distention, the substance of the bone degenerates, and is transformed into a diversified mass, but more or less analogous to that of cancer of the soft parts: while the local and general symptoms still more strikingly resemble those of the latter disease.—(See *Traité des Mal. Chir. t.* 3, *p.* 587.)

According to this writer, all the bones are liable to such a disease; but it has been more frequently observed in the bones of the face, those of the base of the skull, the long bones of the limbs, and particularly the ossa innominata, which are perhaps oftener affected than any other bones of the body.—(*Op. cit. p.* 588.)

Foreign surgeons do not appear to entertain precisely the same ideas respecting cancer which prevail in England: at least, they apply the term to many complaints in which there are no vestiges of a carcinomatous structure, and numerous diseases of an incurable nature receive abroad very indiscriminately the name of cancer. Thus, the French surgeons have not yet distinguished the strongly marked differences between carcinoma and fungus hæmatodes.—(See *Roux, Parallèle de la Chir. Angloise, &c.;* and the article *Fungus Hæmatodes.*)

Mr. Bell, of Edinburgh, has very different opinions of cancer of the bones from those delivered by the preceding writers. Cancer, he says, seldom occurs in bone as a primary affection, but is in almost every case the result of that kind of degeneration in the neighbouring soft parts. He believes, also, that it is propagated through the medium of the cellular tissue, which lines the canals and cells of bones.—(*On Diseases of Bones, p.* 146.) In treating of cancer of the breast, I have adverted to examples, in which the bones participated in the disease. In the museum of the College of Surgeons at Edinburgh, are two specimens of the sternum similarly affected. Mr. Bell's views of the cancer of the bones, however, do not correspond to those taken by Sir Astley Cooper; and it is questionable whether the morbid change of a bone in the vicinity of a cancerous part be itself really malignant. At all events, the kind of caries with fetid discharge, described by Mr. Bell, is very different from the disease spoken of by Sir A. Cooper, where the peculiarity consists in the deposition of a scirrhous substance into the texture of the bone in the advanced stage of carcinoma.

Fungous diseases in the antrum expand the bones of the face, make their way out, and present a frightful specimen of disease. This change of the bones, though known to have nothing to do with cancer (see *Antrum*), is considered by Boyer as a kind of osteosarcoma, proceeding from carcinomatous mischief in the neighbouring soft parts; and this he adduces as an example of his first species of osteosarcoma, or that arising in consequence of previous disease in other parts. In the second species, the disorder commences in the bones, and the soft parts are secondarily affected. In all cases, osteosarcoma comes on with deeply-seated pain, which sometimes lasts a considerable time before any swelling is manifest. Sometimes the pain becomes more and more afflicting, and of the lancinating kind, impairing the health even before there is any change in the form of the limb. At length the swelling takes place, occupying the whole circumference of the member. Its nature and situation are in some measure indicated by its hardness and depth. It is unequal and tuberculated, as it were. Pressure does not lessen its size nor make the pain worse. The soft parts are still in their natural state. The tumour, however, grows more or less rapidly, and the lancinating pains become more severe. In time, the soft parts themselves inflame and become painful. Sometimes the skin ulcerates, and in this very uncommon case the sore presents a cancerous appearance. Hectic symptoms are induced, the patient gradually loses his strength, and at length falls a victim to the disease.

The alteration which the structure of the bones undergoes in osteosarcoma (says Boyer), deserves great attention. Most frequently, when the disease has made considerable progress, and the tumour has existed a long while, the bony texture has disappeared more or less completely; in lieu of it, a homogeneous, grayish, yellowish, lard-like substance is found, the surface of a slice of which is smooth, much like that of a very hard white of egg, or old cheese, the consistence varying from that of cartilage to that of very thick bouillie. The surrounding soft parts, which have participated in the disease of the bones, are converted into a similar matter: muscles, tendons, periosteum, ligaments, vessels, cellular substance, all are confounded in the same homogeneous mass, and have undergone the same degeneration.

In some examples, the disease is less advanced: portions of the bone are then met with whose texture and consistence are nearly natural, and which are merely somewhat enlarged. But in proceeding towards the centre of the disease, the substance of the bone is found softened, and its consistence less than that of cartilage, still manifestly retaining, however, a fibrous texture; while, more deeply, it is converted into a lard-like substance, resembling (says Boyer) that of parts affected with carcinoma. In these tumours cysts are often found sometimes containing a fetid ichor,—sometimes a matter like clear bouillie; and, in certain cases, a quantity of semi-transparent, tremulous, gelatinous matter is found in the middle of the lard-like medullary, or cerebral substance. Boyer records an instance in which nearly the whole humerus was changed into a gelatinous mass.—(See *Mal. des Os, t.* 1, *chap.* 22.) From the variety of substances found to compose dif

ferent osteosarcomatous swellings, various names have been assigned to them; as the cartilaginous degeneration of bone, the fleshy, the cystic sarcoma, the encysted medullary sarcoma, &c.—(See *Bell on Bones*, *p.* 133.)

With the view of removing some of the obscurity of the present subject, Dr. Cumin, of Glasgow, proposes that the term osteosarcoma should be limited to a degeneration and morbid growth of the lining membranes of the longitudinal canals, or cancelli of bones, accompanied in all cases by absorption of the solid osseous substance. "The disease (he says) is, therefore, essentially one of destruction of the affected bone, which is produced partly by the pressure of the enlarging tumour, and partly by the diversion of the fluid circulating within the bone to the support of this morbid growth. It always originates within the periosteum, and retains that as its investing membrane." It is generally slow in its progress; and, in its commencement, the symptoms cannot be readily distinguished from those of chronic rheumatism, or syphilitic pains. After some time a tumour is perceived, at first firm, but afterward becoming softer, and, in certain cases, communicating to the surgeon's hand the feel of a distinct pulsation, synchronous with that of the artery of the limb, and capable of being interrupted by compressing the trunk of the vessel. In time, hectic fever, colliquative perspirations, and diarrhœa come on, and the patient sinks. Towards the close of the illness, fracture of the bone at the affected part very commonly takes place on some slight exertion, aggravating in a remarkable manner the patient's general distress, but rather lessening than increasing the pain in the bone, connected with distention of its texture.—(*Cumin, in Edinb. Med. Journ. No.* 82, *p.* 13.)

This gentleman, in considering the question whether osteosarcoma is of a cancerous nature, expresses his belief, that although all the varieties of the disease are highly formidable, they are not all truly cancerous. One case, which he has himself related, he sets down as cancerous on account of the whole of the symptoms, and "more especially from the disease having shown itself in two different places at the same time;" which, however, abstractedly considered, is not a very good criterion of cancer. Another case, described by him, he does not regard as having exhibited any features of the latter disease. The osteosarcoma of Dr. Cumin is, in fact, as he has himself explained, the *fungous exostosis of the medullary membrane of Sir Astley Cooper.*—(See *Edinb. Med. Journ. No.* 82, *p.* 17.)

The prognosis of this disease must always be unfavourable; for it is equally incurable, and disposed to bring on fatal consequences, whether Boyer's opinion concerning its being cancer of the bones be true or not. This author notices that, even after amputation, the complaint almost always recurs.—(*P.* 591.) The only chance of relief, however, obviously depends upon the possibility and success of the operation. In the *Traité des Mal. Chir. t.* 3, *p.* 594—605, Boyer records two cases of osteosarcoma: one of the thigh; the other of the os innominatum. The first patient was saved by amputation. Osteosarcoma is the disease for which Dr. Mott successfully removed one-half of the lower jaw, very nearly as far as the joint.—(See *American Med. Recorder.*) And Dr. M'Clellan, of Philadelphia, a few years ago, favoured me with the particulars of another case of osteosarcoma of the lower jaw, where the same operation was very skilfully executed.—(See *Boyer, Traité des Maladies Chir. t.* 3. *Haller's Element. Physiol. t.* 8, *p.* 2, *page* 5. *S. A. Kulmus, Diss. de Exostosi Steatomatode Clavículæ: Gedan.* 1732. *S. F. Hundertmark, Diss. sistens Osteosteatomatis Casum rariorem; Lips.* 1752. *S. G. Hermann, Diss. de Osteosteatomate, Lips.* 1767. *S. C. Plenck, de Osteosarcosi; Tub.* 1781, *&c. B. C. Brodie, in Pathol. and Surgical Obs. on the Joints, p.* 301. *Dr. Cumin, in Edinb. Med. Journ. Jan.* 1825. *B. Bell, on Diseases of the Bones*, 12*mo. Edinb.* 1828.

[This disease, the *osteosarcoma* of Boyer, and the *malignant exostosis* of Sir Astley Cooper, has attracted a large share of public attention during the last few years, and especially in this country, in consequence of the extensive and formidable operations to which it has given origin, and the great success which has attended them.

The etiology and pathology of the disease is still a subject of controversy. By some it is viewed as scrofulous, by others carcinomatous, while many consider it identical with fungus hæmatodes. Cases are reported, however, in which the disease was purely local, without exhibiting any malignant or specific character: these, however, are esteemed by those who contend for its being always constitutional, as not belonging to the genus osteosarcoma. A more probable theory is, that the disease is generally, if not always, local in its commencement, but very soon affects the constitution secondarily; at the same time it must be conceded that it is seldom found except in persons of depraved habit of body, either by age, hardships, exposure, or intemperance.

Osteosarcoma is almost universally incurable except by the amputation or excision of the morbid tumour, and the frequent success of these operations may be considered a conclusive argument in favour of its local origin; while the instances of the return of the disease, not a few of which are admitted to have taken place after the operation, may be attributed to the late period at which the knife is resorted to, the constitution having been involved in the morbid action by its long continuance. In these cases, it cannot be expected that the removal of the tumour by the operation should always protect the patient from a return of the disease.

Under the article *Jaw-bone*, in this Dictionary, I have referred to numerous cases of amputation of considerable portions of the lower jaw, all of which, so far as I am informed, were rendered necessary by this disease, so that it would seem that it is most frequently found in this bone. Dr. Mott has performed this operation six times on the lower jaw, and twice taken out the bone at the articulation.

Dr. David L. Rogers of this city, was among the first in this country who removed the *upper* jaw-bone, which he did in a case of osteosarcoma in the year 1824. This case is recorded in the N. Y. Medical and Physical Journal, vol. 3, page 301. It has since been very frequently repeated in this country and in Europe. Dr. Mott has performed it thirteen times, but, so far as I am informed, none of these cases have as yet been published.

In the American Journal of the Medical Sciences for Nov. 1828, a case of osteosarcoma of the left clavicle, in which exsection of that bone was successfully performed by Dr. Mott, is reported at length. This is the first and probably the only operation of the kind ever attempted; and as it is undoubtedly the most difficult and formidable in ancient or modern surgery, I have thought proper in this place to give a description of its performance in the operator's own words, he having politely complied with my request in furnishing me his notes and those of his pupils on the progress of the case.

The tumour was of a conical form, of about four inches in diameter at its base, and of an incompressible hardness, situate on the anterior portion of the clavicle, to which it was firmly attached. The apex of the tumour was covered with luxuriant fungous granulations, the consequence of escharotics previously applied, from which profuse bleedings took place at short intervals.

"An incision was commenced over the articulation of the clavicle with the sternum, and carried, in a semicircular direction, as close to the fungous projections as the sound integuments would admit of, until it terminated on the top of the shoulder, near the junction of the clavicle with the acromion process of the scapula. This incision exposed the fibres of the pectoralis major, which was divided as near the tumour as possible: in accomplishing this, as well as the first incision, arteries sprung in every direction, and required ligatures. A number of large branches of veins, under this muscle, emitted blood freely, and required to be tied.

In conducting the incision through the pectoral muscle, towards the scapular extremity of the clavicle, care was taken to avoid the cephalic vein, as it passes between this and the deltoid muscle. A small portion of the latter muscle was detached from the clavicle, which readily allowed the vein to be drawn outwards towards the shoulder.

On attempting to pass the fore-finger under the vein and deltoid to the lower edge of the clavicle, it was found impracticable, as the hard osseous part of the tumour extended beyond this point, and was com-

pletely in contact with the coracoid process of the scapula.

Finding it impossible, from the size of the tumour, and its proximity to the coracoid process, to get under the clavicle in this direction, an incision was made from the outer edge of the external jugular vein, over the tumour, to the top of the shoulder. After dividing the skin, platysma myoides, and a portion of the trapezius muscle, a sound part of the clavicle was laid bare at a point nearer the acromion than a line with the coracoid process: a steel director, very much curved, was now cautiously passed under the bone from above; which, from the firm, bony state of the tumour at this part, had a considerable obliquity outwards. Great care was taken to keep the instrument in close contact with the under surface of the bone. The depth of the bone from the surface rendered it somewhat difficult to accomplish this safely: an eyed-probe, similarly curved, conveyed along the groove of the director a chain saw, which, when moved a little, showed that nothing intervened between it and the bone; the clavicle was then readily sawed through.

The dissection was now continued along the under surface of the tumour, below the pectoralis major; here a number of very large arteries and veins required tying. The first rib being next exposed under the sternal extremity of the clavicle, the costo-clavicular or rhomboid ligament was divided, and the joint opened from the lower part. This gave considerable mobility to the diseased mass, and encouraged us to believe that its complete removal would be practicable.

By means of a double hook and elevator, with the assistance of our strong and very broad spatulas properly curved, we were enabled to elevate a little the sawed end of the clavicle. After loosening the parts about it, by keeping close to the tumour, we wished to discover the subclavius muscle, as it is inserted in the bone about this situation; but it could not be seen, as it was incorporated with the diseased mass. Had this muscle been found, the separation of the tumour would have been much less difficult and tedious, as, by keeping above it, the subclavian vein is of course protected. The origin of this muscle, from the cartilage of the first rib, was seen and divided, but it was almost immediately obliterated in the tumour.

Continuing the removal of the tumour at the upper and outer part, the omo-hyoideus was found lying under it, which we exposed from where it passes under the mastoid muscle, to near its origin from the superior costa of the scapula. In separating the tumour from the cellular and fatty structure, between the omo hyoid muscle and the subclavian vessels, a number of large arteries were divided, which bled freely, and particularly a large branch from the inferior thyroidal.

The anterior part of the upper incision was now made from the sternal end of the clavicle, and carried over the tumour, until it met the other at the external jugular vein. After cutting through the platysma myoides, this vein was carefully separated from the surrounding parts, and two fine ligatures passed beneath it, and tied a short distance from each other; the vein was then cut between the ligatures.

The clavicular part of the sterno-cleido-mastoideus was next divided, about three inches above the clavicle in the direction of this incision. The deep-seated fascia of the neck being now exposed, the mastoid muscle and the diseased mass, were very cautiously separated from it, until the anterior scalenus was exposed.

The subclavian vein, from the edge of the scalenus anticus to the coracoid process, was so firmly adherent to the tumour, as to lead me at one moment to believe that the coats of the vein were so intimately involved in the diseased structure, as to render the complete removal of the morbid part utterly impracticable. By the most cautious proceeding, however, alternately with the handle and blade of the knife, we finally succeeded in detaching the tumour, without the least injury to the vein. This part of the operation was attended with peculiar danger and difficulty. At every cut either an artery or vein would spring, and deluge the parts until secured by ligatures. Besides several large veins, the external jugular was so situated in the midst of the bony mass, as to require two more ligatures in this place, near to the subclavian, and it was again divided in the interspace. Near the sternal end of the clavicle, a large artery and vein required tying: they were considered as branches of the inferior thyroidal artery and vein.

From having cut through the clavicular portion of the mastoideus muscle, obliquely upwards and outwards a little above the tumour, we were enabled, by turning this down, and keeping close to the fascia profunda, to detach the tumour from over the situation of the thoracic duct and junction of the internal jugular and left subclavian, without the least injury to these important parts.

To reach the lower part of the tumour, as it extended upon the thorax, it was necessary to separate the pectoralis major in a line with the fourth rib, and to make a transverse incision two inches in length through the integuments and muscles at about its centre. The incision upon the neck extended from the sterno-clavicular junction in a semicircular direction, to within an inch of the thyroid cartilage and base of the lower jaw, and two inches from the lobe of the ear, and terminated near the junction of the clavicle and scapula.

The fungous and bleeding character of the apex of the tumour implied that it was freely supplied with vessels. The discharge of blood was so free at every step of the operation, that about forty ligatures were applied. It was estimated that the patient lost from sixteen to twenty ounces of blood.

All the parts now presenting a healthy appearance, the ligatures were cut close to the knots, and the cavity of the wound filled with lint. Long strips of adhesive plaster were applied to prevent the edges of this extensive wound from farther retracting; a light compress, a single-headed roller loosely applied around the chest and shoulders, completed the dressing.

He was placed in bed upon his back, inclining a little to the right side, with the head considerably elevated, while the left shoulder and arm were supported by a pillow.

To the unwearied attentions of two of my pupils I am indebted for the following report of his symptoms.

June 17th, 1828, 7 o'clock, P. M. Feels comfortable, except being nauseated by the wine and water given him during the operation, which he says generally produces this effect upon him. Some reaction is indicated. Between 7 and 8 P. M. took two cups of gruel, and has since vomited a little. 9 P. M. Pulse 110; skin moist and cool. He feels tolerably comfortable, and is much gratified that the operation has been performed. Took a little mint tea, which was grateful to him. 12 P. M. Has had a short repose; drank some mint tea, and feels quite comfortable; pulse 128; thirst considerable.

June 18th, 3 A. M. Has had a comfortable sleep, during which there was considerable hemorrhage from the wound; pulse 120, hard and full. 8 A. M. Took a cup of tea, ate a piece of toast, with a few strawberries; feels better than previous to the operation; pulse 124. 12 P. M. Has slept during two hours, and is now in a comfortable sleep; pulse 130; skin moist and warm."

From this time nothing occurred to interrupt his recovery, and it would therefore be unnecessary to insert here the minutes taken of the daily improvement which was manifest under the judicious management to which he was subjected. It will be sufficient to say that the patient entirely recovered, and has ever since enjoyed excellent health. The concluding remarks accompanying Dr. Mott's report of the case, are perhaps too important to be omitted.

"The tumour is about the size of a man's doubled fists, or of a circumference just to allow me to grasp it with my fingers fully extended. It consists of a bony cup, incompressibly hard at all parts, except superiorly and inferiorly to a small extent. From an opening of an elliptical shape at the upper part, protruded a bleeding fungus of the size and shape of half a hen's egg. At the under surface, as it lay upon the great subclavian vessels, the bony character is less manifest; the structure about the centre particularly appearing to be cartilaginous or semi-osseous. This bony enlargement occupies the clavicle from the sternal articulation to within half an inch perhaps of the acromial extremity. From the motion which can be given to each end of the clavicle, the natural structure of the bone seems to be entirely destroyed.

This operation far surpassed in tediousness, difficulty, and danger, any thing which I have ever witnessed or performed. It is impossible for any descrip-

tion which we are capable of giving, to convey an accurate idea of its formidable nature. The attachment of the morbid mass to the important structure of the neck and shoulder of *the left side*, and to so great an extent, is sufficient to indicate its magnitude and difficulty.

The extensive nature of this operation led us to take the precaution of securing the external jugular with a double ligature, and dividing it between them. Though in operating upon the neck we have several times cut these veins without any unpleasant consequences, we however think we have witnessed almost fatal effects from the division of a large vein, and the admission of air into the circulation.

The case of Baron Dupuytren's, in which a young woman suddenly died under an operation, from the division of a large vein in the neck, while he was engaged in removing a tumour, contributed, with my own experience, to make me take the precaution of previously tying the vein in this operation.

In an attempt which I made to remove the parotid gland in an enlarged and scirrhous state, the facial vein, where it passes over the base of the lower jaw, was opened in dissecting the integuments from the tumour, in the early stage of the operation, before a single artery was tied. At the instant this vessel was opened, the attention of all present was arrested by the gurgling noise of air passing into some small opening. The breathing of the patient immediately became difficult and laborious, the heart beat violently and irregularly, his features were distorted, and convulsions of the whole body soon followed to so great an extent as to make it impossible to keep him on the table. He lay upon the floor in this condition for near half an hour, as all supposed in *articulo mortis*. As the convulsions gradually left him, his mouth was permanently distorted, and complete hemiplegia was found to have ensued. An hour and more elapsed before he could articulate, and it was nearly a whole day before he recovered the use of his arm and leg. From a belief that these effects arose from the admission of air into the blood-vessels, which was not doubted by any person present, I instantly called to mind a set of experiments which I made some twenty years since upon dogs, by blowing air into the circulation, by inserting a blow-pipe into a large superficial vein upon the thigh, and was forcibly struck with the similarity of result.

No adverse symptoms of a general or local nature took place to interrupt the process of granulation in the wound. The immense chasm which was left, and such important parts as have been described, only covered with lint, necessarily occasioned me great solicitude, until I saw suppuration fully established and the great vessels covered by granulations.

No difficulty attended keeping his shoulder in a proper position by the use of the common apparatus for fractured clavicle. With this he walked about without any inconvenience, after four weeks elapsed, and two months from the time of the operation, he was able to discontinue the sling, and by means of an apparatus contrived by Mr. James Kent, a most ingenious and inventive artist, to supply the want of clavicle, he was so fitted as to have his shoulder in its proper position, at the same time that the full motion of his arm was preserved."—*Reese.*]

[OVARIAN TUMOUR. The following highly important and interesting case, having been politely communicated to me by Dr. David L. Rogers of this city, is of so great practical importance, that I have concluded it would be acceptable to the profession to have the description of the operation and its result inserted entire. Very many are annually falling victims to this disease, who might be preserved by a similar operation.

"In July, 1829, I was requested to operate on a woman for peritoneal dropsy; after drawing off the water, I observed that the abdomen remained unusually large; upon examination I discovered a large tumour occupying the left iliac region, and extending to the right side. She gave the following history of its origin and growth. Two years since, in her passage from Ireland to this country, after being two weeks at sea, she had a suppression of the catamenia, which was soon followed by a sharp lancinating pain in the left iliac region; previous to which, her health had always been good. On landing, the pain increased, and the abdomen began to swell; first, on the left, and then extending to the right; her stomach became affected, and although unmarried, her friends accused her of being pregnant.

In consequence of this impression, the disease was allowed to proceed without any medical advice, until time had satisfied her friends to the contrary, when a physician was called, who pronounced the disease a dropsy, and recommended her to be tapped.

A large quantity of water was drawn off, but in two months it had reaccumulated, and the operation was repeated five times previous to my seeing her. It is computed that within the two years, eighteen gallons of fluid were drawn off.

I observed in this case, what I have remarked in several others, that the fluid discharged differed from the water in common ascites. It is much more mucilaginous; of the consistence of honey; of a milky colour, and differs from any other secretion that I am acquainted with. After deliberately examining the tumour, and as far as possible ascertaining its character and connexions, I suggested to her the possibility of its being cured by an operation, at the same time stating the great risk of life attending the performance, and the slight chance of her recovery. I likewise requested Professor Mott, who was consulted in this case, to make a similar statement. Her good constitution and general health all urged the obligation of making an attempt to save her. After the first suggestion, nothing could alter her determination to forego the chance of relief which even so desperate an operation might afford, and, as she expressed it, "I would rather die than live in my present situation."

On the 14th of September, she was laid on a table of convenient height, and with a large scalpel I commenced an incision a little below the ensiform cartilage, carrying it parallel with the linea alba, and terminating at the symphysis pubis. The integuments being divided, the dissection was continued through the tendon of the linea alba to the peritoneum. This was at first supposed to be much thickened, but by a cautious dissection through a membranous texture to the depth of a quarter of an inch, the water gushed out with considerable force. With a probe-pointed bistoury, the opening was enlarged to the full extent of the external incision, and to our surprise we found that a sac was opened which appeared to fill the whole circumference of the abdomen, and at first its attachment appeared commensurate with its size. It lay in connexion with the liver, stomach, spleen, and bladder. By pulling up the sac it was found that the adhesions were much less than at first expected. It was determined, therefore, to dissect them from the peritoneum and omentum: some of the adhesions were so slight as to be separated by the finger, others by the handle of the scalpel, but the greater part required to be separated by a tedious dissection, and in some parts the adhesions were so close that portions of the peritoneal membrane were removed. These adhesions extended for three or four inches around the umbilicus. After completing this part of the dissection, the tumour was drawn out and supported by an assistant, and the dissection continued: separating it from the ovarian ligament, which required much care, from the large and numerous vessels going to it from this source: the largest was at least the size of a goose-quill. After occupying two hours in the operation, this huge mass of disease was safely removed, and laid on the table. The ligatures were all cut close to the knot, and left to absorption. The wound was closed by sutures, dressed with adhesive straps, lint, a compress and a bandage applied firmly to the abdomen. I place some confidence in the close application of a bandage, as it brings the divided surfaces in contact for the purpose of adhesion, and likewise as an important auxiliary in preventing inflammation. She was then removed to bed; her pulse at this time was feeble, but regular. In the course of the evening, considerable reaction came on, with some heat of skin."

Without pursuing the detail of the progress of the case, it will be only necessary to add that the case progressed without any untoward symptom, and in six weeks from the period of the operation her catamenia had returned and her health entirely recovered.

"The tumour was composed of a large sac, which contained the fluid drawn off in different operations for tapping. One-third of the tumour was solid, con-

taining a fibro cartilaginous substance. It weighed three and a half pounds.

In offering this case, it may be proper briefly to sum up a history of the operations for diseased *ovaria*. It may assist others in forming an opinion of the relative chance of success in future cases. The removal of these tumours by an operation had its advocates in the last century; but the authority of De Haen and Morgagni was raised against them, as doubtful in their results, and impossible in their execution. The first attempt to remove them by an operation was made in 1776, by L. Aumonier, surgeon in chief of the Hospital of Rouen, and is reported as a successful case.—(See *Good's Study of Medicine*, *p.* 423.)

Dr. M'Dowel of Kentucky, has reported three cases in which he operated successfully for tumours in the abdomen, ovarian, and hydatid A doubt exists in relation to these cases; and certainly the mode of describing them is calculated to confirm that doubt. We are bound, however, upon the authority of others, to believe them, notwithstanding the improbabilities connected with their details; and it is much to be regretted that a more circumstantial account of these cases has not been given to the profession.—(See *Med. Chir. Rev. vol.* 5, *p.* 216.)

Professor Smith, of Yale College, has given an interesting case of the successful removal of an ovarian dropsy by an operation. The tumour was small, weighing from two to three ounces, and requiring an incision of three inches in length.—(See *Am. Med. Rec.* 1822.)

In the London Medical Gazette, for 1829, Dr. Hopfer, of Biberback, has reported three cases of extirpation of diseased ovaria, by Carysman. The first was performed in 1819, and proved fatal in thirty-six hours after the operation. The second in 1820. This case was successful, and the woman has since borne children. The third case occurred in the same year, and never recovered from the shock of the operation. Thus of the three cases, but one recovered.

M. Lizars, in the Edinburgh Journal for October, 1820, relates an attempt to extirpate an ovarian tumour, but, unfortunately, on cutting into the abdomen, he found no tumour to remove. This case certainly should not be included in the unsuccessful operations for this disease. The same distinguished surgeon has since reported two cases of the operation, but their results have not been known.

Thus we find in the *twelve* operations that have been performed for the removal of this disease, *seven* have been successful, and two remain doubtful."—*Reese.*]

OXYMURIATIC ACID. Besides the nitrous and nitric acids, other medicines, containing a large proportion of oxygen, and easy of decomposition, have been recommended to be tried as remedies for the venereal disease; viz. oxygenated vinegar, oxalic acid, oxygenated muriate of potash, &c.—(See *Caldwell's Medical Thesis*, *vol.* 1, *p.* 111.) But perhaps nothing has been put to the test of experiment with greater expectation of success than the oxygenated muriatic acid. Mr. Cruickshank made a very early trial of it in syphilitic cases, and, as is alleged, with the utmost benefit. He also employed the nitric acid and the oxygenated muriate of potash, and found them eligible remedies. The latter medicine was likewise given by M. Alyon in cases of chancre and secondary ulcers, who found the good effects from it more expeditious and more certain than those of any mercurial preparation.—(*Essai sur les Propriétés Médicinales de l'Oxygène*, &c. 8vo. *Paris, an* 7ème.) On the other hand, as much contrariety of sentiment respecting the real and permanent efficacy of all these medicines prevails in the numerous reports about them, as in the accounts delivered of the effects of the muriatic and nitric acid; and therefore I do not think that the reader, after the copious statements given in this book concerning the *nitric* and *nitrous acids* (see *these words*), would be pleased to hear again a repetition of very similar contradictions respecting the oxygenated muriatic acid. I may observe, however, that if oxygen be the principle on which the efficacy of many antisyphilitic remedies truly depend, this acid must possess greater virtue than the common muriatic acid. From ℥ ss. to ʒ ij. mixed in ℥ viij. of water sweetened with syrup, may be taken in divided doses in the course of the day.

Oxygenated muriatic acid was strongly praised by Guyton de Morveau, as a means of disinfecting sick rooms and purifying the air of crowded hospitals.

OZÆNA. (From ὄζω, a stench.) An ulcer situated in the nose, discharging a fetid purulent matter, and sometimes accompanied with caries of the bones. Some authors have signified by the term, an ill-conditioned ulcer in the antrum. The first meaning is that which mostly prevails. The disease is described as coming on with a trifling tumefaction and redness about the ala nasi, accompanied with a discharge of mucus, with which the nostril becomes obstructed. The matter gradually assumes the appearance of pus, is most copious in the morning, and is sometimes attended with sneezing and a little bleeding. The ulceration occasionally extends around the ala nasi to the cheek, but seldom far from the nose, the ala of which, also, it rarely destroys. The ozæna is often connected with scrofulous and venereal complaints. In the latter cases, portions of the ossa spongiosa often come away. After the complete cure of all venereal complaints, an exfoliating dead piece of bone will often keep up symptoms similar to those of the ozæna, until it is detached. Mr. Pearson remarks, that the ozæna frequently occurs as a symptom of the cachexia syphiloidea. It may perforate the septum nasi, destroy the ossa spongiosa, and even the ossa nasi. Such mischief is now more frequently the effect of the cachexia syphiloidea, than of luos venerea. The ozæna must not be confounded with abscesses in the upper jaw-bone.—(See *Antrum.*)

The constitutional disease on which the ozæna generally depends, and which acts as the remote cause, must be relieved before a cure of the local effect can be expected. The internal medicines which may be necessary are, preparations of mercury and antimony; sarsaparilla, elm, bark, Peruvian bark, muriated barytes, and muriate of lime. Sea-bathing may also do good by improving the health. The best external applications are said to be preparations of copper, zinc, arsenic, mercury, the pulvis sternutatorius, and diluted sulphuric acid.—(*Pearson's Principles of Surgery*, *chap.* 12. *F. A. Mayer, Commentatio de Ozæna, Frank. Del. op.* 11.)

P

PANA'RIS. (From παρὰ, near, and ὄνυξ, the nail.) See *Whitlow.*

PANNUS. When two or three pterygia of different sizes occurred on the same eye, with their points directed towards the centre of the cornea, where they met, and covered all the surface of this transparent membrane with a dense pellicle, the ancients named the disease *pannus.*—(*Scarpa*, *chap.* 14.)

PARACENTE'SIS. (From παρακεντέω, to perforate.) The operation of tapping or making an opening into the abdomen, thorax, or bladder, for the purpose of discharging the fluid confined in these parts in cases of ascites, empyema, hydrothorax, and retention of urine. Effused blood may also require an opening to be made into the chest; and so may confined air in the instance of emphysema.

TAPPING, OR PARACENTESIS ABDOMINIS.

When the swelling extends equally over the whole abdomen, the fluid is usually diffused among all the viscera, and is only circumscribed by the boundaries of the peritoneum. The water is occasionally included in different cysts, which are generally formed in one of the ovaries; and in this case, the tumour which is produced is not so uniform, and the fluctuation not so distinct, as in peritoneal dropsy, at least, while the disease has not made great progress. The difference also in the consistence of the fluid, may

render the fluctuation more or less difficult of detection. When the water is contained in different cysts, it is frequently thick and gelatinous; but when it is uniformly diffused all over the cavity of the peritoneum, it is generally thinner, and even quite limpid. Sometimes a considerable number of hydatids are found floating in the fluids. With regard to the symptoms of common ascites, the disease is attended with great uneasiness, from all kinds of pressure on the abdomen; a gradual swelling of this part of the body, not inclining more to one side than the other; a fluctuation perceptible when the surgeon lays his hand on one side of the tumour and gently taps on the opposite side of it; considerable difficulty of breathing caused by the collection of fluid interrupting the action of the diaphragm, and obliging the patient to lie with his chest very much raised; constant thirst, &c. According to Sir A. Cooper, the most common cause of ascites is disease of the liver, which has the effect of impeding the circulation of the blood in the vessels of most of the other abdominal viscera. He also enumerates as other causes, an enlargement of the spleen, which presses upon and irritates the peritoneum, so as to determine an increased flow of blood to it, and an effusion of serum; great debility of the system induced by fevers or mercury; diseases of the heart and lungs; in which cases, the ascites is generally combined with hydrothorax.—(See *Lancet, vol.* 3, *p.* 2.)

Whatever may be the efficacy of digitalis, mercury, diuretics, and calomel, elaterium, squills, and other evacuants, in ascites, they are rarely of any service in cases of local and encysted dropsies. When such swellings continue to enlarge, notwithstanding the adoption of a few measures which will presently be suggested, the sooner the fluid is evacuated the better. It is also well known, that all efforts to produce a radical cure, even of dropsies which are not encysted, too frequently fail. I am decidedly of opinion, however, with Dr. Fothergill, that physicians would meet with much more success in the treatment of ascites if they were to recommend paracentesis to be done sooner than they generally do. This operation is, for the most part, much too long delayed; and during a long space, the bowels are continually suffering more and more, from the effect of the large quantity of fluid which oppresses them. What ought to render the practice of early tapping more entitled to approbation is, that the operation, when done in the situation which will be presently advised, is perfectly free from danger, attended with very little pain, and need not interrupt the farther trial of such medicines as the physician may place confidence in. Paracentesis only becomes a serious measure when the disease has existed for a great length of time, and the patient has been much weakened by it. Indeed, there seems much reason to suspect that the operation should be done as soon as the tension of the abdomen and the fluctuation leave no doubt concerning the nature of the malady; especially when the first trials which have been made of internal remedies seem to promise no success. Dr. Fothergill has demonstrated by facts, the advantages of this method. On the commencement of an ascites, this celebrated practitioner advises the trial of diuretics and other evacuants. He then adds, that "if by a reasonable perseverance in this course no considerable benefit accrues; if the viscera do not evidently appear to be obstructed, and unfit for the purposes of life; if the complaints have not been brought on by a long habitual train of intemperance, and from which there seems little hope of reclaiming the patient; if the strength and time of life are not altogether against us; I desist from medicine, except of the cordial kind, and let the disease proceed, till the operation becomes safely practicable. When this is done, by the moderate use of the warmer diuretics, chalybeates and bitters, also the preparations of squills in doses below that point at which the stomach would be effected, I endeavour to prevent the abdomen from filling again."—(*Med. Obs. and Inq. vol.* 4, *p.* 112.) The same author remarks, with regard to encysted dropsies, that tapping sometimes effects a radical cure.

The operation should not only be performed in as early a stage of the disease as is compatible with the safety of the parts within the abdomen, it should also be repeated as soon as the quantity of fluid accumulated again is sufficient to make the puncture practicable without danger. Desault used to tap dropsical patients once a week, and in many cases, after he had performed the operation two or three times, the disease was stopped.

However, with respect to early tapping in ascites, one fact, mentioned by Sir A. Cooper in his lectures, ought to be known, namely, that dropsy arising from the debility caused by fever or a course of mercury, and attended with diseased liver, spleen, or disorganization of other important organs, may often be cured by medical treatment without any operation at all; and he therefore disapproves of paracentesis in such cases, as long as the fluid is not sufficiently copious to hinder the risk of the bowels being hurt by the trocar. As soon as this risk ceases, however, the practice seems commendable, because it will rather promote than retard the good effect of any other means which may be deemed advisable. At the same time, I ought to mention the opinion of the above distinguished practitioner, that the operation itself will never bring about a cure, except where the disease has proceeded from the debility left by some kind of fever or the abuse of mercury.

The great number of times that the operation has been repeated in some individuals is surprising: for instance, twenty-nine times (*Schmucker, Wahrnehmungen, b.* 2, *p.* 102); forty-one (*Med. Communications, vol.* 2); fifty-two (*Schmucker, vol. cit. p.* 187); sixty-five (*Mead*); one hundred (*Callisen, Syst. Chir. Hodiernæ, vol.* 2, *p.* 55); one-hundred and fifty-five (*Phil. Trans. vol.* 69); and if it be possible to credit Bezard, even six hundred and sixty-five times upon one woman in the course of thirteen years. When the patient died, the peritoneum was found to be three lines in thickness. The omentum mesentery, and even the liver, gall-bladder, spleen, pancreas, kidneys, and bladder, had almost disappeared, a schirrous mass containing pus occupying their place towards the right side.—(See *Bulletin de la Société Méd. d'Emulation, No.* 12, *Dec.* 1815.)

Whenever a considerable quantity of fluid is suddenly let out of the abdomen by tapping, the quick removal of the pressure of the water off the large bloodvessels and viscera may produce swooning, convulsions, and even sudden death. These consequences led the ancients to consider paracentesis as a very dangerous operation, and when they ventured to perform it, they only let out the water gradually, and at intervals.

Dr. Mead, after considering what might occasion the bad symptoms resulting from too sudden an evacuation of a large quantity of fluid from the abdomen, was led to try whether external pressure would prevent such consequences. It was conceived, that in this way he might keep up the same degree of pressure which the fluid made on the viscera. The success attending some trials of this plan fully justified the opinion Dr. Mead had entertained; for when the compression is carefully made, the whole of the water contained in the abdomen of a dropsical patient may be safely discharged as quickly as the surgeon chooses. For this purpose, however, the whole abdomen must be equally compressed, the pressure increased in proportion as the evacuation takes place, and kept up in the same degree for several days afterward. While the water is flowing out, the necessary degree of pressure is usually made with the sheet which is put round the abdomen. Two assistants, who hold the ends of the sheet, gradually tighten it, in proportion as the fluid is discharged. Immediately after the operation, some folded flannel, sprinkled with spirit of wine, is laid over the whole anterior part of the belly, and covered with a broad linen roller, applied with due tightness round the body. Dr. Monro invented a particular kind of belt for the purpose; but though it may be well adapted to the object in view, it is, perhaps, unnecessary, as the above method seems to answer every end.

The instrument used for tapping the abdomen is called a trocar.—(See *Trocar.*) Of this there are several varieties; but Richter and many other experienced surgeons give a decided preference to the common trocar. Most of the modern alterations which have been made in the construction of trocars have only tended, says Richter, to render their employment more difficult. There is no reason for the ordinary objection, that the common trocar cannot be introduced without considerable force. If the part into which it is about to be passed be made tense, very little force will be necessary, especially if care be taken to rotate the instrument gently, as well as push it for

wards. Hence, all the inventions which have originated from this supposed imperfection, are represented by Richter to be entirely useless. He condemns the trocar with a double-edged point as a bad instrument. The proposal of Mr. Cline, to make a puncture with a lancet first, and then to introduce into the opening a blunt-pointed trocar is alleged to be superfluous. Nay, these innovations are declared to be worse than useless. A cutting instrument is liable to injure blood-vessels, and bring on a weakening degree of hemorrhage; and it is said, that the wound thus made does not heal so readily as that made with a common trocar. That sharp-edged instruments are attended with the inconvenience of being apt to wound enlarged veins, and produce an unpleasant degree of hemorrhage, is a truth of which I have myself met with a convincing example. A female, who had a strong aversion to being tapped with a trocar, prevailed upon me to make the opening with a lancet. The puncture was made in the linea alba, about three inches below the navel. A stream of dark-coloured venous blood continued to run from the wound the whole time the water was flowing out of the cannula, and did not cease until a compress was applied. The quantity of blood lost could not be less than a pint, or a pint and a half. In many cases, the loss of so much blood would prove fatal to dropsical patients, and is what one must always feel anxious to avoid.

The position commonly selected for the operation is that in which the patient sits in an arm-chair. However, weakness and other circumstances frequently make it necessary to operate on the patient as he lies on his side sufficiently near the edge of the bed; and this posture has one decided advantage, viz. that it tends to prevent the alarming syncope, which the sudden removal of the pressure of the fluid from the diaphragm and abdominal viscera almost always brings on in the erect position.

Until of late, the place in which surgeons used to puncture the abdomen, in cases of ascites, was the centre of a line drawn from the navel to the anterior superior spinous process of the ileum, and on the left side, which was preferred, in consequence of the liver not being there. The place for the puncture was usually marked with ink, and was supposed to be always situated just over a part of the linea semilunaris, where there is no fleshy substance, nor any large blood-vessel, exposed to injury. This calculation, however, was made without considering that, in dropsy, the parietes of the abdomen do not yield equally in every situation. On the contrary, it is known that the front is always more distended than the lateral parts, and that the recti muscles in particular are sometimes very much widened. In consequence of these alterations, induced by the disease, no dependence can be put on any measurement made with the view of ascertaining the precise situation of the linea semilunaris. The surgeon who trusts to his being able to introduce the trocar exactly in this place, from any calculation of the above kind, will frequently wound a great thickness of muscle, instead of a part where the abdominal parietes are thinnest. But a still stronger objection is to be urged against the practice of attempting to tap in the linea semilunaris. Men well acquainted with anatomy have frequently been deceived in their reckoning, and, instead of hitting the intended line with their trocars, they have introduced these instruments through the rectus muscle, and wounded the epigastric artery. Patients have died from this error with large extravasations of blood in the cavity of the peritoneum. In a dropsical person who has been tapped, it is to be observed also, that an effusion of blood in the abdomen will of course more readily take place, in consequence of the parts not being in the same close, compact state in which they are in the healthy condition.

Henceforth, therefore, let every prudent practitioner abandon the plan of tapping in the linea semilunaris; and he may the more easily make up his mind to do so, as there is another place where the operation may be done with the utmost facility and safety. The linea alba is now commonly preferred by the best surgeons; because here no muscular fibres need be wounded, the place can be hit with certainty, and no large blood-vessel can be injured. About the middle point between the navel and pubes, is as good a situation for making the puncture as can possibly be chosen. The surgeon should introduce the trocar in a steady, firm manner, never in an incautious, sudden way, lest parts contained in the peritoneum should be rashly wounded. For the same reason, immediately the point of the trocar has entered the abdomen, a thing always known at once by the sudden cessation of resistance to its passing inwards, it should be introduced no farther, and its office of making a passage for the cannula is already accomplished. The surgeon, consequently, is now to take hold of the cannula with the thumb and index finger of his left hand, and gently insinuate it farther into the cavity of the peritoneum, while with his right hand he is to withdraw the stilet. The fluid now gushes out, and regularly as it escapes, the sheet which is round the patient's body is to be tightened. All the water having been evacuated, a piece of flannel and a roller are to be immediately applied, as above explained, a piece of lint and soap-plaster having been previously applied to the wound.

It is not uncommon for the water suddenly to stop long before the full quantity is discharged. Sometimes this happens from a piece of intestine or omentum obstructing the cannula. This kind of stoppage may be removed by just introducing a probe or director, and holding the portion of bowel back. When the water is viscid, the only thing we can do is to introduce a large trocar, if doing so should promise to facilitate the evacuation. Also, when hydatids obstruct the cannula, a larger instrument might allow them to escape. In encysted dropsies, the practitioner of course can only let the fluid out of those cavities which he can safely puncture. According to Sir Astley Cooper, the water of encysted dropsy is at first contained, not in a single bag, but in several, the partitions between which are in time gradually absorbed, and the number of distinct cavities consequently diminished. Hence another reason why the fluctuation becomes more evident as the disease advances.—(*Lectures, &c. vol.* 2, *p.* 373.) The fact should also influence the surgeon not to make too early a puncture, which could only discharge the fluid from one cyst, while several others, not having yet any communication with it, would remain distended.

The abdomen of a female was tapped by Dr. Andrew Buchanan through the fundus of the bladder, for which purpose a tube with a stilet was introduced by the meatus urinarius. The method was adopted chiefly for the purpose of trying what would be the result of maintaining, in ascites, a communication between the cavity of the peritoneum and that of the bladder. In the case referred to, the water was discharged; but success did not attend the endeavour to keep the puncture in the fundus of the bladder open.—(*Buchanan, in Glasgow Med. Journ. vol.* 1, *p.* 195.) It seems to me, that any means calculated to perpetuate the opening would be likely to cause peritonitis. The continuance of an opening between the cavity of the bladder and that of the abdomen, owing to the irritating qualities of the urine, can hardly be viewed as free from serious risk. There is an analogy between this suggestion and that of Mr. Guy of Chichester, who proposed leaving the cannula in the wound, and occasionally letting the water flow out after the ordinary mode of paracentesis; a plan, however, which is attended with less risk, and has sometimes been followed by a cure.—(See *Sir Astley Cooper's Lectures vol.* 2, *p.* 383.)

When a dropsy of the ovary is very large, it also admits of being tapped in the linea alba; but in this particular case, it is generally best to make the puncture where the swelling is most prominent. In this disease, the ovary is either converted into one large cavity, filled with fluid, or else it contains several distinct cells. Sometimes the cyst consists of the membranous covering of the ovary; sometimes of an enormous hydatid. The contents are sometimes exceedingly viscid. In the early stages of the case, the tumour is situated towards one side of the abdomen, just above Poupart's ligament, and seems to ascend out of the pelvis. This kind of progress at once distinguishes the disease from a common ascites, which is attended from the first with an equal, gradual, universal swelling of the abdomen. The magnitude (which the disease may attain) may be judged of by the fact, that twelve or fifteen gallons of fluid have sometimes been contained in the cavity or cavities of the cyst. The cyst of the ovary, when it has attained a large size, generally adheres, in different places, to the inner surface of the peritoneum, and in this state the whole abdomen often

seems uniformly swollen, in consequence of the immense magnitude of the disease.—(See *G. D. Motz, De Structurâ, Usu, et Morbis Ovariorum, 4to. Jenæ*, 1788.) It is an observation made by Sir A. Cooper, that one of the principal differences between ascites and ovarial dropsy, is that the latter is in itself quite a local disease, just like a hydrocele. This observation, I believe, is perfectly correct; and though great illness frequently arises, it is generally the result of the pressure made by the swelling on the parts within the abdomen and pelvis. The impairment of the health, arising from the pressure of the viscera and interruption of their functions, and the great difficulty of breathing produced by the pressure of the diaphragm, indeed make it necessary to let out the fluid, and paracentesis must be done in the way already related. The disease is often attended with an almost total stoppage of the secretion of urine. Sometimes the urine is duly secreted, but a retention occurs, so that the use of the catheter becomes indispensable. With few exceptions, tapping can only be regarded as a palliative measure: the water collects again, the same grievances recur, and the operation must be repeated. While an ovarial dropsy is recent, and even after it has been tapped, some attempts may be made to effect a radical cure. But this is not to be done with mercury, or any other medicine yet known. Blistering the surface of the abdomen, keeping up a discharge with the savine cerate, and applying a tight roller, have been known to do good. In France, the celebrated Le Dran laid open the cysts of ovarial dropsies. His patients did not die of the consequent inflammation, and the dropsy, indeed, was cured; but there remained either a sarcomatous enlargement of the ovary, which continued to increase till death, or else incurable fistulæ, leading into the cyst. The large size of a wound necessary for this purpose, the danger of inducing inflammation in so extensive a surface as the cyst of a large ovarial dropsy, and the events of Le Dran's cases, are circumstances, on the whole, which ought to keep the practice from ever being revived.

A still more absurd plan has been attempted, viz. to cure the disease by injections like hydroceles. I formerly saw two cases in which port wine and water were injected by the late Mr. Ramsden of St. Bartholomew's Hospital: one patient died very soon afterward of inflammation, and the other perished more lingeringly from the same cause. Setons have been tried without success.

In the American Recorder, a case is published, in which a cure was effected by the excision of the sac. Dr. N. Smith also performed such an operation with success: after exposing the tumour by an incision, and discharging seven pints of a dark, ropy fluid with a trocar, he extracted the whole cyst, and the patient recovered.—(See *Edin. Med. and Surg. Journ. No.* 73.) The sac brought out with it a considerable portion of adherent omentum, which required to be separated with the knife, and two bleeding vessels were tied. The omentum was then reduced, and the adhesions of the sac to one point of the parietes of the abdomen also separated partly with the scalpel and partly with the finger. These few particulars show, that though the operation may be practicable, and even end well, it is liable to great difficulties in its execution, and dangerous and fatal consequences in its result. In fact, one surgeon, mentioned by Sir A. Cooper, who began an operation of this kind, was prevented by the extent of the adhesions from completing it. Whenever the attempt is made, it ought to be while the cyst is of moderate size. An instance in which the operation was attempted while the disease did not exist, has been fairly and candidly laid before the public by M. Lizars, with other interesting observations and cases in favour of the practice of extirpating diseased ovaries.—(*Edinb. Med. Surg. Journ. No.* 81.)

An example is mentioned by Dr. Granville, in which several encysted tumours of the right ovarium (one as large as a full grown fœtus's head) were discharged, with a collection of matter, through an ulcerated opening in the parietes of the abdomen.—(See *Med. Phys. Journal, June*, 1822.)

Sir A. Cooper has known several examples of the spontaneous cure of ovarian dropsy. In one case, the fluid was for a long time voided through an ulcerated opening at the umbilicus. He has also known the water to be discharged by the Fallopian tube; and he attended a lady in whom an ovarian cyst burst into the intestinal canal: for several years afterward she was subject to occasional returns of the disease, but ultimately recovered.—(*Lectures, vol.* 2, *p.* 384.)

PARACENTESIS OF THE THORAX.

The necessity for this operation is indicated when the heart or lungs are oppressed by any kind of fluid confined in the cavity of the chest. Every body knows that the free and uninterrupted performance of the functions of these organs is essential to the support of life. When their action is perilously disturbed by the lodgement of fluid in the thorax, no internal medicines can be much depended upon for procuring relief. The only means from which benefit can be rationally expected, is letting out the fluid by making an opening in the parietes of the chest.

The nature of the effused fluid can make no difference in regard to the propriety of discharging it in this manner; and though some authors describe this operation as only applicable to cases of hydrops pectoris and empyema, it may also be of the greatest service when air is confined in the chest (see *Emphysema*), or blood extravasated there (see *Wounds of the Thorax*), so as to make dangerous pressure on the lungs and diaphragm. The case in which it is least likely to be followed by a perfect recovery is hydrothorax; and Sir A. Cooper, in his vast experience, has not known more than one operation performed for it, which proved unsuccessful. This he considers by no means surprising, as the collection of fluid is the effect of disease of the thoracic viscera, the heart, or lungs, &c.—(*Lectures, vol.* 2, *p.* 385.) A case of success, however, is mentioned in the references at the end of the present article; and in the *Berlin Med. Trans.* a case is recorded, in which a cure was effected by an accidental wound of the chest, by which the whole of the water escaped at once.—(*Act. Med. Berol. t.* x, *dec.* 1, *p.* 44.)

The idiopathic form of hydrothorax, or that case in which it constitutes the original disease, is set down by Laennec as very rare. He has often known hypertrophy of the heart, aneurism of the aorta, irregular consumption, and even schirrhus of the stomach or liver mistaken for this disorder, when there was no coexisting effusion in the pleura, or at least none except what took place immediately before death. Symptomatic hydrothorax, he admits, is very frequent.—(*On Diseases of the Chest, p.* 484, *ed.* 2.) In this work, the learned translator Dr. Forbes recommends the use of the stethoscope for discriminating diseases of the heart from hydrothorax, as the means adapted to the relief of dropsy of the chest would be useless with regard to them.

In this place I shall content myself with describing the best method of performing paracentesis thoracis, referring the reader to the above articles and the valuable work of Laennec, for the particular symptoms and circumstances which may render the operation proper, and the rest of the surgical treatment peculiar to each affection.

The safest and most convenient situation for making an opening into the chest, is between the sixth and seventh true ribs, on either side, as circumstances may render necessary. The surgeon should always recollect, that the two cavities of the pleura are completely distinct from each other and have no communication whatsoever; so that if fluid were contained on the left side of the thorax, making an opening into the right cavity would not serve for discharging the accumulated matter. The practitioner should also remember, that when there is a fluid on both sides of the chest, paracentesis must never be done for the relief of the two collections at the same time; because there is great reason to believe, that, as the lungs on one side usually collapse when there is a free communication between the air and inside of the thorax, they would do so on both sides were an opening made at the same time into each bag of the pleura. It is hardly necessary to remark, that in this condition the patient could not breathe, and would die suffocated. The operation consists in making an incision, about two inches long, through the integuments which cover the space between the sixth and seventh true ribs, just where the indigitations of the serratus major anticus muscle meet those of the externus obliquus. Here it is unnecessary to divide any muscular fibres except those of the intercostal muscles, and, by putting the patient in a proper

posture, the opening that is to be made will be depending enough for any purpose whatsoever. The surgeon, avoiding the lower edge of the upper rib where the intercostal artery lies, is then cautiously to divide the layers of the intercostal muscles till he brings the pleura into view, when this membrane is to be very carefully divided with a lancet. The instrument should never be introduced deeply, lest the lungs be injured. The size of the opening in the pleura should never be larger than necessary. The discharge of blood and matter will of course require a freer aperture than that of air or water. If requisite, a cannula may be introduced into the wound, for the purpose of facilitating the evacuation of the fluid; and it may even in some cases be proper to let this instrument remain in the part, in order to let the water or pus escape as often as another accumulation takes place. It is obvious, however, that a cannula, for this object, should only be just long enough to enter the cavity of the pleura, and should have a broad rim to keep it from slipping into the chest. A piece of sticking-plaster would easily fix the cannula, which might be stopped up with a cork or any other convenient thing, or left open, according as the circumstances of the case and the judgment of the surgeon should direct.

Paracentesis of the abdomen, and that of the thorax, are described in all treatises on the operations and systems of surgery. The works of Sharp, Le Dran, Bertrandi, Callisen, Richter, Sabatier, Larrey, and Boyer, are particularly deserving attention. A case in which eleven pints of a fluid, resembling whey, were discharged from the chest by paracentesis, and the patient recovered, is detailed by Dr. Archer in the Trans. of the King's and Queen's Colleges of Physicians in Ireland, vol. 1, *art.* 1. *Jackson, in Philadelphia Journal of the Med. Sciences, vol.* 1. *New Series, p.* 119; *operation performed in a Case of Effusion. N. Friedreich, Vorzüge des Bauchstiches in der Bauchwassersucht,* 12*mo. Wurzb.* 1816, 1817. *Laennec on Diseases of the Chest, ed.* 2, *by Forbes. Good's Study of Medicine, vol.* 5, *ed.* 3.

For an account of the paracentesis of the bladder refer to *Bladder, Puncture of.* Consult also *Emphysema, Empyema,* and *Wounds of the Thorax.*

PARAPHYMO'SIS, or Paraphimosis. (From παρά, back, and φιμόω, to bridle.) This signifies the case in which the prepuce is drawn quite behind the glans penis and cannot be brought forward again. See *Phymosis,* with which it will be considered.

PARONY'CHIA. (From παρὰ, near, and ὄνυξ, the nail.) An abscess at the end of the finger near the nail. See *Whitlow.*

PAROTID DUCT. Every one acquainted with anatomy is aware, that behind the jaw, on each side, a large conglomerate gland is situated, the principal of such as are destined to secrete the saliva with which the cavity of the mouth, and the food which we swallow, are continually moistened. The parotid duct crosses the cheek, being situated about one-third from the zygoma, and two-thirds from the basis of the jaw. After passing over the masseter muscle, it pierces the buccinator, and terminates in the mouth by a considerable orifice, opposite the space between the second and third bicuspid grinders of the upper jaw. As soon as it has passed the masseter, it dives deeply into the fat of the cheek, and, as M. Louis observes, makes an angle before it opens into the mouth.—(*Mém. de l'Acad. de Chir. t.* 3, *p.* 457.)

On account of its situation, the parotid duct is liable to be wounded, and this has even been done with the surgeon's lancet through ignorance.—(See *Monro's Works, p.* 520.) In cases of this kind, the continual escape of saliva may prevent the wound from healing, and what is called a *salivary fistula* would be the perpetual consequence if no steps were taken to afford relief. The parotid duct has sometimes been ruptured by blows.—(*Œuvres Chir. de Desault, t.* 2, *p.* 221.) Cases also occur, in which the face becomes considerably swollen, in consequence of the saliva insinuating itself into the cellular substance, just as air does in emphysema. Respecting the last circumstance, I shall only just mention, that mischief of this kind may always be prevented from becoming very extensive, by making a depending opening for the ready escape of the fluid.

With regard to the treatment of salivary fistulæ, if the division of the parotid duct is recent, the sides of the wound should be brought into contact, and a steady pressure maintained on that part of the cheek by means of suitable compresses and a roller. In this manner a salivary fistula may often be prevented altogether; either the divided ends of the duct reunite, and the spittle resumes its original course into the mouth; or what is more probable, the wound in the face heals at every part, with the exception of a small fistulous track, which serves as a continuation of the duct into the cavity of the mouth. The latter kind of cure, however, can only take place when the wound extends quite through the cheek; but the chance of the two portions of the duct uniting and becoming continuous again, should always be taken in recent cases.

When a salivary fistula is actually formed, a seton introduced from the external fistulous orifice into the mouth, is a method which has justly received considerable approbation. Monro adopted it with success: he kept in the seton till the channel which it had formed had become fistulous, after which it was withdrawn: the external orifice being touched with the argentum nitratum healed up, and the saliva in future flowed through the artificial fistulous channel into the mouth.

Desault used to practise the seton as follows: he introduced two fingers of his left hand into the patient's mouth, and placing them between the teeth and the cheek, opposite the fistula, thus kept the integuments tense, and the gums from being injured. He then introduced a small hydrocele trocar with its cannula just before the opening of the posterior part of the duct, and pushed it through the cheek in a direction a little inclined forward. An assistant now took hold of the cannula, while Desault withdrew the perforator, and passed through the tube a bit of thread into the cavity of the mouth. The cannula was then taken out, and a seton, which was then fastened to the end of the thread in the mouth, was drawn from within outwards; but not so far as to come between the edges of the external opening, where the thread alone lodged, and this was fastened with sticking-plaster to the outside of the cheek. The outer wound was dressed with lint and compresses. Desault used to change the seton daily, introducing regularly rather a larger one, and taking especial care not to bring it between the edges of the wound, which was afterward covered with sticking-plaster. He enjoined the patient not to move the jaw much, and only allowed him, for some time, liquid food. In about six weeks he used to omit the seton, leaving in the thread, however, for a little while longer. This being taken away, he used to finish the cure, by touching the little aperture remaining with caustic.

The making of an artificial passage is one of the most ancient plans of curing salivary fistulæ. Every author has had his particular method of doing it, and numerous variations are to be met with, either in the instrument employed for piercing the cheek, or in the substance intended for maintaining the opening. For the first step of the operation, surgeons sometimes used the actual cautery, as Saviard furnishes us an instance of; sometimes an awl, as Monro did; sometimes a common knife or lancet; sometimes a straight needle, which drew in the thread after it; but Desault's trocar is to be preferred to such means, because the cannula, by remaining in the wound after the perforator is withdrawn, allows the thread to be introduced, which in every other way is either difficult to accomplish, or requires the use of several instruments.

For the second step of the operation, viz. keeping the opening distended, cannulæ were employed by Duphenix, who used to make a suture over them; a plan objectionable, inasmuch as it was attended with the inconvenience of a solid body left in the parts, and also that of the instrument being apt to slip into the mouth. M. Beclard lately cured a salivary fistula by the formation of a new passage at the inside of the cheek, by means of a leaden style, which was made to reach the excretory duct, at the point where its continuation was interrupted. The outer opening was then made a fresh bleeding wound, and united with the twisted suture. This is the second example of the success of the method in the hands of this able practitioner. When the case will admit of the employment of the twisted suture, Beclard's plan is a good one, because the cure will be more speedily effected by it than the seton. (See *Monro's Works. Œuvres Chir. de Desault, par Bichat, t.* 2, *p.* 221. *Also Mém. de l'Acad. de Chir. t.* 3. [7] *B. Siebold, Diss. sistens Historiam Systematis*

Salivalis physiologice et pathologice considerati, fol. Jenæ, 1797 *Beclard, in Archives Gén. de Méd. Juin*, 1823.)

PAROTID GLAND, EXTIRPATION OF.—(See *Tumours.*)

[This organ was successfully removed in 1826 by Dr. Prieger, on account of a carcinomatous affection of it. The mass taken out weighed two pounds and three quarters. The patient, a woman 35 years of age, completely recovered. The operation was finished in seven minutes. About 16 or 18 ounces of blood were lost. The large arteries were tied as soon as divided; viz. the auricular, the external maxillary, and the branches of the external carotid distributed to the gland itself.—(See *Journ. für Chirurg., &c., herausgeben von D. L. Graefe, &c., D. P. F. Walther, b.* 2, *st.* 3.)—*Pref.*]

[For the following remarks on the extirpation of the parotid gland, I am indebted chiefly to Dr. Gross's edition of "Tavernier's Operative Surgery," and the New-York Medical and Physical Journal; never having witnessed the operation myself. Indeed, until entire success had attended the operation in Europe, and again in Philadelphia, I confess myself to have been among those who doubted the practicability of the operation, and very much questioned the fact of its having ever been removed. It is well known, that Allan Burns, Boyer, Richerand, and other distinguished surgeons, have all expressed themselves strongly against the possibility of this operation. But the paper of M. Pillet, of Lyons, sustained before the Medical Faculty of Paris in 1828, has fully established the possibility of the operation, and he has cited a number of successful cases.

To deny that the parotid gland has ever been extirpated, would be to impeach the veracity of some of the most skilful anatomists and surgeons who adorn the present age. That the operation is dangerous and difficult of execution no one will presume to dispute; but to assert that it cannot be performed, is not only absurd, but altogether incompatible with the present state of surgery. Can it be supposed that such men as Beclard and Sir Astley Cooper, whose names are known in every part of the world where medicine is cultivated as a science, would be guilty of publishing cases which never had any existence? Those who will candidly examine the cases on record, will be convinced, not only that the operation is practicable, but that it has been actually performed.

In the year 1823, Professor Beclard performed this operation. This patient died a few days afterward, and it was readily ascertained that the surgeon was not deceived. The year following it was repeated by M. Gensoul, and a second time in 1828, successfully in both instances. Without referring to the numerous cases reported, in relation to some of which there is room to doubt, I will only mention the cases of Goodlad, Carmichael, Lisfranc, Manfredini, Idrae, Kirby, Sir Astley Cooper, the two cases of Professor M'Clellan of Philadelphia, and a case within a few weeks by Professor Bushe of New-York, in all which there is no possibility of doubt, but the whole parotid gland was removed by the knife, and in most of them with entire success.

The conclusions drawn from this mass of testimony are these: viz. 1st, That the parotid, in a scirrhous state, can be entirely extirpated; 2d, that the carotid and its larger branches are necessarily implicated in the operation; and, 3dly, that it is impossible to spare the fascial nerve, and therefore that paralysis is an inevitable consequence.

With regard to the propriety of securing the carotid before commencing the operation, it is worthy of remark, that Mr. Goodlad's case was the only one in which it was performed. In MM. Beclard's, Lisfranc's, Gensoul's, Carmichael's, one of M'Clellan's, and Bushe's, it was tied during the operation, while in Dr. Prieger's, Mr. Kirby's, and one of Dr. M'Clellan's, the trunk of the external carotid was left untouched. Although it may be a measure of security, yet there is no urgent reason why it should precede the removal of the parotid, and there must be many cases in which, from the size of tumour, it would be impracticable.

It is not generally known, and though strictly true, it will be very reluctantly admitted, that this operation was first performed in this country. Professor Samuel White, of Hudson, successfully extirpated the whole of the parotid for a scirrhous tumour as early as the year 1808, and although the case was soon after published, and the patient has been frequently examined since by the most distinguished surgeons of the state, all of whom satisfied themselves that the whole of the gland is removed, yet it will be found that the operation was not subsequently attempted in Europe until 1823, nor in America until 1826. Dr. White is now professor of surgery, jointly with his son, in the Berkshire Medical Institution, to both of whom I have had occasion to refer in my notes of American surgery.—*Reese.*]

PARU'LIS. (From *παρὰ*, near, and *οὖλον*, the gum.) An inflammation, boil, or abscess in the gums.

PE'NIS, AMPUTATION OF. No part of the penis should ever be amputated, on account of a mortification, because the dead portion will be naturally thrown off, and the ulcer heal, without the least occasion for putting the patient to any pain by the employment of the knife. Some cancerous and fungous diseases are the cases in which it is often really proper and necessary to amputate more or less of this organ.

However, before a surgeon ventures to do the operation, he ought to be certain that it is the substance of the penis which is incurably diseased; for, as that judicious surgeon, Callisen, remarks, tumours, excrescences, ulcers, and gangrenous mischief of the prepuce, sometimes present appearances which may lead an inexperienced practitioner to fancy the whole thickness of the part affected with irremediable disorder, while the glans is actually in a sound state. Hence, when ever the least doubt exists, it is better to remove first the prepuce and skin, in order that the true condition of the glans may be detected.—(*Systema Chirurgiæ Hodiernæ, pars posterior*, p. 420. *Hafniæ*, 1800.)

The old surgeons, fearful of hemorrhage, used sometimes to extirpate a part of the penis, by tying ligatures round it with sufficient tightness to make it mortify and slough off. Thus Ruysch once performed the operation.—(See *Obs.* 30.) The plan, however, is exceedingly painful, and, notwithstanding the authority of Heister, has been most properly rejected from modern surgery.

The amputation may be done in the following manner:—A circular incision is to be made through the skin, about a finger-breadth from the cancerous part. As Callisen observes, it is hardly ever requisite to draw the skin back before it is cut; because, after the corpora cavernosa are divided, they retract so considerably, that there is always a sufficiency of the integuments.—(*Syst. Chir. Hodiernæ, pars posterior*, p. 421.) As soon, therefore, as the circular incision through the skin has been made, the corpora cavernosa and urethra are to be cut through, by one stroke of the knife, on a level with the cut edges of the integuments. Sabatier even advises us to draw the skin towards the glans penis, before we employ the knife; so convinced is he of the inutility of saving any of it, and of the inconveniences which may result from its lying over and obstructing the orifice of the urethra. His mode of operating is also particularly simple, as he cuts through the integuments and penis together by one stroke of the knife, without making any preliminary circular division of the skin. (*Médecine Opératoire, t.* 3, *p.* 305, *edit.* 2.)

The bleeding arteries are now to be immediately tied: the chief are, one on the dorsum of the penis, and one in each corpus cavernosum. When a general oozing from the wound still continues, some recommend (*White, Hey, &c.*) applying sponge to its surface; others (*Latta*) finely-scraped agaric, with a small proportion of pounded white sugar, or gum-arabic. Perhaps, however, finely-scraped lint supported with compresses would be quite as effectual as any styptics, and certainly, the latter applications should be avoided, if possible, because stimulating and productive of pain and inflammation. A surer and preferable method of stopping the oozing of blood, and at the same of healing the wound, might be to bring the skin forwards over the end of the stump, with two strips of sticking-plaster, after introducing a flexible gum catheter into the continuation of the urethra, so as to keep its orifice unobstructed, and the urine from coming into contact with the wound. There can be little doubt, that the gum catheter would be better than a silver one, or any metallic cannula, commonly advised for the above purposes, because it lies in the passage with less irritation. It is but justice to Callisen to state, that he seems to be one of the few good surgical writers who have particularly recommended in these cases the elastic

gum catheter, in preference to that made of silver.—(*Op. cit. p.* 421.) The French method of fixing the catheter in the urethra is an excellent one, and has been described in the article *Catheter*. In one case in which Mr. Hey operated, he made a longitudinal division of the integuments at the inferior part of the penis, so as to make them cover its extremity without puckering, or lying over the orifice of the urethra. The corpora cavernosa, however, do not readily granulate, and unite to the skin by the first intention.—(*Hey, p.* 452.) After the first dressings have been removed, the part should be dressed with the unguentum cetaceum.

In consequence of the introduction of a cannula being neglected, Le Dran saw the orifice of the urethra close a few hours after the operation, so that the patient could not make water. The orifice of the passage could not be discovered without great difficulty. A lancet being introduced at the point against which the urine seemed to be forced, a quantity of it gushed out, and, as a cannula was not at hand, a sound was introduced till one could be procured.—(*Traité des Opér. de Chirurgie.*)

Mr. Pearson advises the skin not to be drawn back, because, when saved in this manner, it impedes the free exit of the urine. He also disapproves of introducing cannulæ, as painful and unnecessary (*On Cancerous Complaints, p.* 103); but Le Dran's experience, and that of the best modern practitioners, will not justify the latter statement.

When the penis is amputated near the pubes, the remainder shrinks under that bone and within the integuments so far, that it is difficult to tie the arteries. In order to obviate this inconvenience, Schreger recommends the skin to be drawn forwards and fixed with a band; then an incision to be made just deep enough to divide the dorsal arteries, which are to be tied before the knife is used again. The incision is then to be continued perpendicularly till the two arteries of the corpora cavernosa are cut. These are now to be tied. Then the corpus spongiosum and its two arteries are to be cut through, which last are to be secured. Lastly, the rest of the skin of the penis is to be divided. In this way Schreger amputated a diseased penis, of which only a part, about an inch in length, was sound.

Sharp, Le Dran, Bertrandi, Sabatier, and C. Bell's books on the operations, may be consulted. Hey's Practical Obs. in Surgery, p. 445. *Pearson on Cancerous Complaints, p.* 103, *&c. Lips.* 1816. *Roux, Voyage à Londres, &c. fait en* 1814. *Wadd, Cases of Dis. of the Prepuce and Scrotum. J. H. Thaut, Diss. de Virgæ Virilis Statu sano et morb. ejusdem imprimis Amputatione. B. G. Schreger's Chir. Versuche; Neue Methode den Penis zu Amputiren, b.* 1, *p.* 242, *8vo. Nurnberg* 1801.

PENIS, CANCER OF. A wart or a tubercle on the prepuce, the frænum, or the glans penis, is generally the first symptom, and it often remains in a quiet state for many years. When irritated, however, it becomes painful, and enlarges, sometimes enormously, in a very short time. At the same time, ulceration and a discharge of sanious fetid matter take place. The disease sometimes also occasions in the urethra fistulous openings, out of which the urine escapes, and the lymphatic glands in the groin may become affected as the disease advances. Mr. Pearson says, that "cancerous excrescences have a broad base, often more extensive than their superficies; they seem to germinate deeply from within, or rather to be a continuation of the substance of the part; and, in their progressive state, the contiguous surface has a morbid appearance." What he considers as a venereal wart, has a basis smaller than its surface: its roots have rather a superficial attachment, and the contiguous parts have a natural appearance.—(*P* 97.) Such are this gentleman's marks of discrimination. We might question, however, whether Mr. Pearson, notwithstanding his great opportunities, ever saw a really *venereal* wart. For many years I never saw any excrescences of this kind in St. Bartholomew's Hospital which truly required mercury for their cure, or which, when cured without it, were followed by any inconvenience. If my memory does not fail me, Mr. Abernethy also disbelieves in the doctrine of venereal warts.

Foul, spreading, sloughy ulcers of the penis should be discriminated from cancer; and likewise diseases produced and kept up by local irritation of the prepuce (See *Earle's Obs. in Med. Chir. Trans. vol.* 12, *p.* 287, *&c.*) It is worthy of attention, that almost all the cases of cancer of the penis recorded by Mr. Hey were attended with a congenital phymosis. The same complication also existed in another example, in which Boyer performed amputation of the penis in La Charité on account of a cancerous affection of the part. In the only two opportunities of doing this operation which M. Roux has had, the cases were likewise accompanied with a natural phymosis. Hence this author considers such a state of the prepuce particularly conducive to cancer of the penis, and earnestly enjoins surgeons to recommend their patients to have the first inconvenience rectified, so that no risk of the other more serious affection may be encountered.—(See *Parallèle de la Chirurgie Angloise, &c. p.* 306, 307.) In two out of three cases which were reported to be cancerous, and for which amputation was done under my notice, it did not appear that any degree of phymosis existed.—(See *Pearson on Cancerous Complaints. Hey's Practical Obs. in Surgery. Roux, Voyage fait en Angleterre en* 1814, *ou Parallèle de la Chir. Angloise, &c. p.* 306.)

PERINÆ'UM, FISTULÆ OF.—(See *Fistulæ in Perinæo.*)

PE'RNIO. (From *πέρνα*, or *πτέρνα*, the heel.) A chilblain, especially one on the heel.—(See *Chilblain.*)

PESSARY. (From *πέσσω*, to soften.) The intention of pessaries, among the old practitioners, was to keep medicinal substances applied within the pudenda. They are now never made use of, except for preventing a prolapsus of the uterus or vagina, or for keeping up a very uncommon kind of rupture, explained in the article *Hernia.*

PHAGEDÆ'NA. (From *φάγω*, to eat.) An ulcer which spreads, and, as it were, eats away the flesh. Hence the epithet *phagedenic*, so common among surgeons. For an account of the *phagedæna gangrænosa*, see *Hospital Gangrene.*

PHARYNGO'TOMY. (From *φάρυγξ*, the pharynx, and *τέμνω*, to cut.)—(See *Œsophagotomy.*)

PHARYNGO'TOMUS. (From *φάρυγξ*, the throat, and *τομή*, an incision.) An instrument for scarifying the tonsils, and for opening abscesses about the fauces. It was invented by Petit, and is nothing more than a sort of lancet, enclosed in a sheath. By means of a spring, the point is capable of darting out to a determinate extent, so as to make the necessary wound, without risk of injuring other parts.

PHLEBO'TOMY. (From *φλὲψ*, a vain, and *τέμνω* to cut.) The operation of opening a vein for the purpose of taking away blood.—(See *Bleeding.*)

PHLE'GMON. (From *φλέγω*, to burn.) Healthy inflammation.—(See *Inflammation.*)

PHLOGO'SIS. (From *φλογόω*, to inflame.) An inflammation. A flushing.

PHRENI'TIS. (From *φρένες*, the diaphragm, supposed by the ancients to be the seat of the mind.) An inflammation of the brain. Phrensy.

Inflammation of the brain is a frequent consequence of injuries of the head. The general symptoms are, an increased and disordered state of the sensibility of the whole nervous system: the retina cannot bear the usual stimulus of light; the pupils are contracted; the pulse is frequent and small; the eyes are red and turgid, and the iris sometimes actually inflamed (*Wardrop, Essays on the Morbid Anat. of the Eye, vol* 2); the countenance is flushed, and the patient is restless, mutters incoherently, and grows wild and delirious The symptoms, however, are very much modified by the degree, extent, and stage of the disorder. Whoever wishes to have a scientific conception of the subject, ought to consult Abercrombie's excellent work, entitled, *Pathological and Practical Researches on Diseases of the Brain, p.* 5, *8vo. Edin.* 1828.

Phrenitis is treated on the antiphlogistic plan. Copious bleedings and other evacuations are highly proper. Blood should be taken from the temporal arteries, or by cupping the temples. The skin ought to be kept moist with antimonials, and after free bleeding and purging, counter-irritation should be excited on the scalp with blisters.

PHY'MA. (From *φύω*, to grow.) Tubercles comprehend eight genera, and we learn from Dr. Bateman, that under the genus *phyma*, the late Dr. Willan intended to comprise the terminthus, the epinyctis, the furunculus and the carbuncle.—(See *Bateman's Synopsis of*

Cutaneous Diseases, p 270, *edit.* 3.) According to Pott, this term was formerly applied to an inflammation near the anus.—(See *Anus, Abscesses of.*)

PHYMO'SIS, or rather PHIMOSIS. (From *φιμὸς*, a muzzle.) A case in which the prepuce cannot be drawn back, so as to uncover the glans penis. It is of two kinds, viz. *accidental*, and *natural* or *congenital*. Both the accidental phymosis and paraphymosis, according to Mr. Hunter, arise from a thickening of the cellular membrane of the prepuce, in consequence of an irritation, capable of producing considerable and diffused inflammation. A chancre is a frequent cause; but a mere inflammation and discharge from the glans and prepuce, and also a gonorrhœa, may bring on these affections. The inflammation often runs high, and is frequently of the erysipelatous kind. The cellular membrane being loose, the tumefaction becomes considerable; and the end of the prepuce being a depending part, the serum often lodges in it, and makes it œdematous. A congenital contraction of the aperture of the prepuce is very common, and persons so affected have a natural and constant phymosis. Such a state of parts (says Mr. Hunter) is often attended with chancres, and it produces very great inconveniences during the treatment. When there is considerable diffused inflammation, a diseased phymosis, similar to the natural one, unavoidably follows; and, whether diseased or natural, it may produce a paraphymosis, simply by the prepuce being brought back upon the penis. This tight part then acting as a ligature round the body of the penis, behind the glans, retards the circulation beyond the constriction, so as to produce an œdematous inflammation on the inverted part of the prepuce.

When the prepuce is very long, phymosis may also arise from the swelling of the glans penis, produced by sores on the latter part, or the irritation of a severe gonorrhœa.—(*Travers, in Surgical Essays, part* 1, *p.* 132.) My own observations lead me to consider an irritation and swelling of the prepuce itself as by far the most common causes of the accidental phymosis.

In some children, the *natural* or *congenital* phymosis is so considerable, that the urine cannot pass with ease; but the aperture of the prepuce generally becomes larger as they grow older, and the bad consequences which the phymosis might have occasioned in disease are thus avoided.

In certain individuals, especially old men, the prepuce sometimes contracts without any visible cause whatever, and becomes so narrow as to hinder the water from getting out, even after it has passed out of the urethra, and, consequently, the whole cavity of the prepuce becomes filled with urine, attended with great pain.

In phymosis, when the prepuce swells and thickens, more and more of the skin of the penis is drawn forwards over the glans, and the latter part becomes at the same time pushed backwards by the swelling against its end. From such a cause, Mr. Hunter has seen the prepuce projecting more than three inches beyond the glans, with its aperture much diminished.

Mr. Hunter also notices, that the prepuce often becomes, in some degree, inverted, by the inner skin yielding more than the outer, and the part seems to have a kind of neck, where the outer skin naturally terminates. From the tightness and distention of the parts, the prepuce now cannot be drawn more back, so as to expose any sores which may be situated under it. This state is frequently productive of bad consequences, especially when there are chancres behind the glans; for the glans being between the orifice of the prepuce and the sores, the matter sometimes cannot get a passage forwards, between the glans and prepuce, and, consequently, it accumulates behind the corona glandis so as to form a kind of abscess, which produces ulceration on the inside of the prepuce. This abscess bursts externally, and the glans often protruding through the opening, the whole prepuce becomes thrown towards the opposite side, and the penis seems to have two terminations. On the other hand (says Mr Hunter), if the prepuce is loose and wide, and is either accustomed to be kept back in its sound state, or is pulled back to admit of the chancres being dressed, and is allowed to remain in this situation till the above tumefaction takes place, the case is then named a *paraphymosis*. Also, when the prepuce is pulled forcibly back, after it is swelled, it is then brought from the state of a phymosis to that of a paraphymosis. The latter case is often attended with worse symptoms than the former, especially when it has first been a phymosis. According to Mr. Hunter, the reason of this is, that the aperture of the prepuce is naturally less elastic than any other part of it; therefore, when the prepuce is pulled back upon the body of the penis, that part grasps it more tightly than any other portion of the skin of the penis, and more so, according to the inflammation. Hence, there are two swellings of the prepuce; one close to the glans, the other behind the stricture. The constriction is often so great as to interrupt the circulation beyond it. This increases the swelling, adds to the stricture, and often produces a mortification of the prepuce itself, by which means the whole diseased part, together with the stricture, is sometimes removed, forming, as Hunter ably expresses himself, a natural cure. In many cases, the skin and prepuce are not the only parts affected; adhesions and even mortifications may also take place in the glans, corpora cavernosa, &c.—(See *Hunter on the Venereal Disease*, *p.* 221, *&c.*)

An accidental phymosis should always be prevented if possible, and therefore, says Mr. Hunter, upon the least signs of a thickening of the prepuce, which is known by its being retracted with difficulty and pain, the patient should be kept quiet; if in bed, so much the better, as, in a horizontal position, the end of the penis will not be so depending. If confinement in bed cannot be complied with, the end of the penis should be kept up, though this can hardly be done when the patient is walking about. The object of this plan is to keep the extravasated fluids from gravitating to the prepuce, which they would hinder from being drawn back again even more than the inflammation itself.

When phymosis is recent, and attended with swelling of the glans or prepuce from inflammation, Mr. Travers recommends injections of tepid water, or milk and water, beneath the foreskin; and the immersion of the penis, three or four times a day, in a tepid bath, keeping the end of the penis upwards; and the use of leeches; which, I think with him and other writers (see *Dict. des Sciences Méd. t.* 41, *p.* 334), should never be put exactly on the swelled prepuce itself. As the inflammation subsides, injections of weak goulard, or the solution of alum, or liquor calcis and calomel, may be substituted.—(*Travers, Surgical Essays, part* 1, *p.* 138.) Instead of warm applications, some practitioners prefer cold: and it is yet an unsettled question which remedies answer best.

When the inflammation is of longer standing, the swelling compresses the urethra, and there is tendency to abscess, ulceration of the latter passage, extravasation of urine, and gangrene of the skin, Mr. Travers advises the employment of emollient poultices and fomentations (the common practice, I believe), and the introduction of a small elastic gum catheter into the bladder. "This (says he) is not a practice indicated by the degree of stricture, which is seldom considerable enough to require it; but by the approaching danger of extravasation. *It should not therefore be taken up, unless the cellular membrane of the penis has advanced to suppuration.*"

As when there are sores they cannot be dressed in the common way, injections must frequently be thrown under the prepuce, or the operation for phymosis performed. Mr. Hunter advises mercurial injections; either crude mercury, rubbed down with a thick solution of gum arabic; or calomel with the same, and a proportion of opium; or else a solution of one grain of the oxymuriate of mercury in one ounce of water. Mr. Hunter also recommends the application of emollient poultices, with laudanum in them, and to let the part, previously to the application being made, hang over the steam of hot water, with a little vinegar and spirit of wine in it.

When, in a case of phymosis, chancres bleed, Mr. Hunter recommends the oil of turpentine as the best stimulus for making the vessels contract; but when the hemorrhage proceeds from irritation, he recommends sedatives. Whatever is used, he says, must be injected under the prepuce. Under such circumstances it has always been a rule with me to avoid irritating applications, and on this account I have never used turpentine, particularly as any troublesome bleeding from chancres may always be effectually checked by covering the penis with linen kept wet with very cold water. When the inflammation has abated, Mr. Hunter advises moving the prepuce occasionally, so as to

prevent its becoming adherent to the glans. He says he has seen the opening of the prepuce so much contracted, from the internal ulcers healing and uniting, that there was hardly any passage for the water. If the passage in the prepuce, so contracted, be in a direct line with the orifice of the urethra, a bougie must be used. If otherwise, the operation of slitting up, or removing part of the prepuce, becomes necessary.

When matter is confined under the prepuce in the manner above described, Mr. Hunter recommends laying the prepuce open from the external orifice to the bottom, where the matter lies as in a sinus or fistula. However, he thinks the performance of this operation for the mere purpose of applying dressings unnecessary, as the sores may be washed with injections by means of a syringe.

I happened to serve my apprenticeship at St. Bartholomew's at a time when the fashion of cutting every phymosis, inflamed or not, was far too common; and I had abundant opportunities of witnessing the irreparable gangrenous mischief frequently thus produced. It gives me pleasure, therefore, to find this villanous practice justly disapproved of by a modern writer. "It is not advisable (says Mr. Travers) to cut the inflamed prepuce, nor indeed any inflamed part. I lately saw a phymosis induced by a thickened and rigid state of the membrane of the prepuce during the free use of mercury, constitutionally and locally, for the cure of two sores, each of the size of a split pea, situated one on each side of the anterior fold of the prepuce. It was the opinion of an eminent surgeon, that those sores, which were thoroughly intractable, would not heal unless the prepuce was freely divided; and impressed with the same idea, after poulticing for some days, I slit it up. The sores immediately healed; but the wound as quickly assumed the same indolent and intractable character which had belonged to the sores, and was so slow in healing that it seemed to be only a transfer of the disease from one part to another." —(*P.* 139.) I have not only witnessed the same fact, in several cases under the late Mr. Ramsden, and in St. Bartholomew's Hospital, but have seen mortification brought on by the still more rash practice of cutting the prepuce, either when the part was in a state of acute inflammation, or there were ulcers within it, when the constitution was in a reduced and very disordered state from the injudicious and immoderate use of mercury.

The common operation for the cure of phymosis consists in slitting open the prepuce nearly its whole length in the direction of the penis. This plan is certainly the most eligible when the matter of a chancre cannot escape from under the prepuce; because circumcision, which many surgeons since Mr. Hunter's time have preferred, would not suffice for giving vent to the accumulated pus. In many cases of phymosis, says Mr. Hunter, an operation is improper; for while the inflammation is very considerable, such a measure might bring on mortification. He acknowledges, however, that there are cases in which a freedom given to the parts would prevent the latter event. When matter is confined under the prepuce, he deems an opening indispensable; and if the patient should object to the common operation, he advises an opening to be made with a lancet directly through the prepuce, or else with caustic.—(See *Hunter on the Venereal Disease*, *p.* 232, *et seq.*)

When the prepuce is to be slit open, a director is first to be introduced under it, and the division is then to be made with a curved pointed bistoury from within upwards.

Many surgeons object to this operation, because the prepuce continues afterward in a very deformed state; and they perform circumcision, or amputation of the prepuce, in the following manner. The prepuce is first taken hold of with a pair of forceps, as much of the part being left out as is judged necessary to be removed. The removal is then accomplished by one sweep of the knife, which, directed by the blades of the forceps, is sure of making the incision in a straight and regular manner. A fine suture is next passed through the edges of the inner and outer portions of the skin of the prepuce, so as to keep them together. The only necessary dressings are lint, and over it an emollient poultice.

Dr. Ryan lately mentioned to me a new plan of operating on phymosis, which is less severe than the common ones, attended with no mutilation, and, according to this gentleman, very effectual. It consists in drawing back, as far as practicable, the external skin of the prepuce, and then insinuating a director under its internal duplicature, and dividing it with a narrow curved bistoury. In some cases, I have no doubt that this method would completely answer, and enable the surgeon to throw a lotion under the prepuce, and even to uncover the glans sufficiently to bring a chancre into view. The method of M. J. Cloquet also merits notice: it consists in slitting the under surface of the prepuce upon a director, in a line parallel with the frænum. When this latter part is very short, it is to be divided with the scissors. The longitudinal wound thus made becomes transverse when the prepuce is drawn back; and scarcely any deformity is the consequence.

At the period when I first entered the profession, it was the custom to salivate every patient who happened to have a phymosis. However, now that the fact of any irritation about the prepuce and glans penis, even that of common warts, being capable of producing the complaint is well known, such absurd practice has been relinquished, and the cause and condition of the disease are always considered previously to the determination for any particular method of treatment. Nay, even when phymosis does arise from chancres, if there be a great deal of inflammation, the use of mercury may rather do harm than good, and the practitioner should not be precipitate in its administration. On this point I fully coincide with Mr. Travers. "Upon many occasions (says he), practitioners are too anxious to contend with the specific character of the venereal disease, to the neglect of the inflammatory state of the affected parts exhibited during its height. The abuse of administering mercury for an acute gonorrhœa and recent sores, accompanied by phymosis, or an approach to that state, is of common occurrence; and it is far from being recognised by the profession as an established rule of practice, that its constitutional administration is inadmissible during the existence of active inflammation in cellular textures."—(*Surgical Essays*, *part* 1, *p.* 131.)

In nine cases out of twelve, in which the experienced Mr. Hey had occasion to amputate the penis for cancerous disease, the patients were also affected with a natural phymosis.—(*Pract. Obs. in Surgery.*) Roux has noticed the same thing in three similar examples; and as he conceives that phymosis may be conducive to carcinoma of the penis, he thinks that it should always be remedied in time.—(*Parallèle de la Chir Angloise*, *p.* 306.)

TREATMENT OF PARAPHYMOSIS.

The removal of the stricture in this case should always be effected, because its continuation is apt to produce a mortification in the parts between the stricture and the glans. It may be done in two ways: either by compressing with the fingers all the blood out of the swelled glans, so as to render this part sufficiently small to allow the constricting prepuce to be brought forwards over it with the aid of the two fingers; or by dividing the stricture with a knife. In a former edition of this work, as Mr. Dunn of Scarborough has reminded me, the power of cold applications, in promoting the reduction of the glans, should have been mentioned. This method should always be put in practice before the reduction by compression is attempted, as a preliminary measure, which sometimes succeeds of itself, and renders unnecessary any painful handling of the parts. From the great success which I have seen attend the first mode, I should not conceive the second one to be so frequently necessary as Mr. Hunter seems to lay down. This operation is always troublesome to accomplish, because the swelling on each side of the stricture covers or closes the tight part, which cannot be got at without difficulty. Mr. Hunter says, the best way is to separate the two swellings as much as possible where you mean to cut, so as to expose the constricted part; then take a crooked pointed bistoury, pass it under the constriction, and divide it. None of the swollen skin on each side should be cut. The prepuce may now be brought forwards, unless it be thought more convenient, for the purpose of dressing the chancres, to let it remain in its present situation.—(See *Hunter on the Venereal Disease*, *p.* 238, 239.)

The original disease producing phymosis and para-

phymosis must always be attended to, and the employment of mercury must be necessary or unnecessary according to the nature of the affection of which these are only effects.

One of the most interesting writers on phymosis and paraphymosis is J. L. Petit, Traité des Mal. Chir. t. 2. Consult also *J. Hunter on the Venereal Disease. Sabatier, Médecine Opératoire, t.* 3, 8*vo. Paris*, 1810. *Travers, in Surgical Essays, part* 1, 8*vo. Lond.* 1818. *There is also a valuable chapter on this subject in Richter's Anfangsgr. der Wundarzn. b.* 6.

PILES.—(See *Hemorrhoids.*)

PILULÆ ARGENTI NITRATIS. ℞. Argenti nitratis gr. iij. Aquæ distillatæ gutt. aliquot. Micæ panis q. s. ut fiant pil. xx. The author of the *Pharmacopœia Chirurgica* suggests the trial of these pills in obstinate leprous and other cutaneous affections, and phagedenic, anomalous ulcers connected with constitutional causes. Two or three may be given twice a day. Dr Powell gave the argentum nitratum internally in a case of hydrophobia, but without any sensible effect.

PILULÆ COLOCYNTHIDIS CUM HYDRAR. SUBM. ℞. Extracti colocynth. comp. ℈ij. Hydr. submur. gr. xii. Saponis ℈j. Misce ut fiant pilulæ duodecim. Two of these pills operate as a purgative, and they are often prescribed in various surgical cases.

PILULÆ CONII. ℞. Extracti conii ℥ss. Pulv. herb. cicutæ q. s. fiant pil. lx. These are the hemlock pills in use at Guy's Hospital. They are occasionally given in scrofulous, cancerous, and venereal cases. The surgeon should begin with small doses, and increase them gradually till nausea and headache arise. From one to a greater number of these pills may be given in this manner every day.

PILULÆ CUPRI SULPHATIS. ℞. Cupri sulphatis gr. xv. Olibani, extracti cinchonæ, sing. ʒij. Syrup. simpl. q. s. fiant pil. lx. From one to four of these pills may be given in a day for gleets.—(*Pharm. Chirurg.*)

PILULÆ HYDRARGYRI. Of these I need only observe here, that the full dose is ten grains (see *Mercury*), but when prescribed as an alterative, from three to five grains will suffice.

PILULÆ HYDRARGYRI OXYDI RUBRI. One grain of this preparation in each pill is the dose, which is commonly taken at bedtime.—(See *Mercury.*)

PILULÆ HYDRARGYRI CUM CONII. ℞. Hydrargyri purificati drach. j. Arabici gummi pulverisati drach. ij. Extracti conii drach. j. Conii foliorum in pulverem tritorum, q. s. The quicksilver is to be first reduced by triture with the gum arabic, moistened with a little rain-water. The inspissated juice of hemlock is afterward to be added, and, lastly, the powdered leaves in sufficient quantity to make a suitable mass for pills. These, with a slight variation in the proportion of the hemlock, are the *pilulæ mercuriales* of Plenck, who directs three or four pills, each of three grains, to be given every night and morning.

No doubt there are many cases to which this formula must be very suitable; for instance, the enlarged prostate gland, and some forms of bronchocele, &c. For such diseases, Dr. Saunders, in his *Formulæ Selectæ*, directs equal parts of pil. hydrarg. and extractum conii.—(*Pharm. Chirurg.*)

PILULÆ HYDRARG. SUBMUR. ℞. Hydrarg. submur. gr. xij. Conservæ cynosbati quod satis sit. M. fiant pil. xii. These are the calomel pills in common use. Surgeons give one or two of them daily, as alteratives, in numerous cases. At Guy's Hospital they add three grains of the pulvis opiatus to each pill, using syrup instead of the conserve.

PILULÆ HYDRARG. SUBMUR. CUM CONIO. ℞. Hydrarg. submur. gr. vj. Extracti conii ʒj. M. fiant. pil. xii. One may be given thrice a day, in scirrhous, cancerous, scrofulous, and some anomalous diseases, resembling venereal diseases.

PILULÆ HYDRARGYRI SUBMUR. CUM ANTIMONIO TARTARIZATO. ℞. Hydrarg. submur. ʒj. Antimon. tart. gr. xv. Opii pur. ℥ss. Syrupi simpl. q. s. fiant. pil. lx.

PILULÆ HYDRARG. SUBMUR. COMPOSITÆ. ℞. Hydrarg. subm. sulph. antim. præcip. sing. gr. xii. Guaiaci gummi resinæ gr. xxiv. Saponis q. s. M. fiant pil. xii. Similar to Plummer's pills. In porrigo, herpetic affections, and many anomalous diseases, they are exceedingly useful. Some diseases of the breast and testicle are also benefited by them.

PILULÆ OPII. These need only be mentioned among such as are of eminent utility in surgery.

PILULÆ OPII COMPOSITÆ. ℞. Opii purif camphoræ, sing. ʒj. Antim. tart. gr. xv. Syrup. simpl. q. s. fiant pil. lx. Used for alleviating pain, and keeping up a gentle perspiration; are particularly useful in preventing painful erections in cases of gonorrhœa, chordee, &c.—(See *Pharm. Chir.*)

PILULÆ QUININÆ. ℞. Quininæ sulphatis gr. xxiv. Confect. rosæ ʒss. Misce et div. in pilulas duodecim. When an alterative treatment is necessary, in conjunction with a tonic plan, I frequently join the sulphate of quinine with the pil. hydrarg. submuriat. comp., the extractum conii, or the blue pill; and in other cases with opium, the pil scillæ c., or the extractum hyoscyami, according to circumstances.

PILULÆ SODÆ CUM SAPONE. ℞. Sodæ subcarbonatis exsiccatæ ʒj. Saponis ℈j. M. fiant pil. xii. Four may be given thrice a day in cases of bronchocele, and indurations of the absorbent glands from scrofula.

PILULÆ ZINCI SULPHATIS. ℞. Zinci sulphatis ʒ ij. Terebinthinæ q. s. fiant pil. lx. One or two are occasionally given in cases of gleets thrice a day.

PLANTARIS MUSCLE. This long slender muscle of the leg is sometimes ruptured in dancing and leaping. The surgeon can do little more than advise rest, antiphlogistic remedies, and the same posture of the limb as in the rupture of the tendo achillis.—(See *Tendon.*)

POLYPUS. A tumour, generally of a pyriform shape, most commonly met with in the nose, uterus, vagina, and antrum, and named from an erroneous idea that it has several roots, or feet, like polypi.

Polypi more frequently grow in the cavity of the nose, than in any other situation, and are visibly of different kinds. One polypus is red, soft, and sensible; but free from pain, and exactly like a piece of healthy flesh: it is the *fleshy polypus* of various writers. When this kind of polypus is of a softer consistence, semitransparent, and of a paler yellowish colour, in consequence of being less vascular, it is called the *gelatinous polypus*, and usually arises from the mucous membrane of the side of the antrum, or the middle of the cavity of the nostril, between the upper and lower turbinated bones. Sir Astley Cooper has never seen a polypus growing from the mucous membrane of the septum narium.—(*Lectures, &c. vol.* 2, *p.* 348.) Other polypi are called *malignant*, being hard, scirrhous, and painful: the *carcinomatous polypi*, as they are named by Sir A. Cooper, and which, according to his statement, are a disease of old age. He also describes another malignant polypus, which he calls *fungoid*, and occurs, as he represents, at all periods of life. It bleeds copiously, but is not so painful as the cancerous disease.—(*Lectures, &c. vol.* 2, *p.* 354.) This distinguished surgeon likewise describes *hydatid polypi*, which generally occur in young people, and the cysts of which may be burst by pressure, and the fluid in them discharged. Richter describes another kind of nasal polypus, which is pale, very tough, and secretes a viscid discharge; which undergoes an alteration of its size with every change of the weather; and which is rather a relaxation, or elongation, of a part of the Schneiderian membrane, than a polypous excrescence. The whole membranous lining of the nostrils is sometimes thus relaxed and thickened.—(*Anfangsgr. der Wundarzn. b.* 1, *kap.* 21.) Besides the preceding varieties of polypi, children are subject, as Sir A. Cooper has explained, to red projections within the nose, which are liable to be mistaken for polypi, but are of a different nature, and may be cured by touching them with the end of a bougie, armed with the argentum nitratum.

Mr. Pott has taken great pains to explain that there is one kind of polypus originally *benign;* another originally *malignant*. He states, that those which begin with, or are preceded by, considerable or frequent pain in the forehead and upper part of the nose, and which, as soon as they can be seen, are either highly red, or of a dark purple colour; those which, from the time of their being first noticed, have never been observed to be sometimes bigger, sometimes less, but have constantly rather increased; those in which coughing, sneezing, or blowing the nose gives pain or produces a very disagreeable sensation in the nostril or forehead; those which, when within reach, are

painful to the touch, or which, upon being slightly touched, are apt to bleed; those which seem to be fixed, and not moveable by the action of blowing the nose, or of driving the air through the affected nostril only (when the polypus is only on one side); those which are incompressibly hard, and which when pressed occasion pain in the corner of the eye and forehead, and which, if they shed any thing, shed blood; those which by adhesion occupy a very considerable space, and seem to consist of a thickening, or of an enlargement of all the membrane covering the septum narium; those which sometimes shed an ichorous, offensive, discoloured discharge; those round whose lower part, within the nose, a probe cannot easily and freely be passed, and that to some height; ought not to be attempted at least by the forceps, nor, indeed, by any other means; and this for reasons obviously deducible from the nature and circumstances of the polypus. On the one hand, the very large extent and quantity of adhesion will render extirpation impracticable, even if the disease could be comprehended within the forceps, which it very frequently cannot; and on the other, the malignant nature of the distemper may render all partial removal, all unsuccessful attacks on it, and, indeed, any degree of irritation, productive of the most disagreeable consequences.

But the polypi which are of a palish or grayish light-brown colour, or look like a membrane just going to be sloughy; which are seldom or never painful, nor become so upon being pressed; which have appeared to be at one time larger, at another less, as the air has happened to be moist or dry; which ascend and descend freely by the action of respiration through the nose; which the patient can make to descend by stopping the nostril which is free, or even most free, and then driving the air through that which the polypus possesses; which when pressed give no pain, easily yield to such pressure, become flat thereby, and distil a clear lymph; and round whose lower and visible part a probe can easily, and that to some height, be passed, are fair and fit for extraction; the polypus, in these circumstances, frequently coming away entire; or if it does not, yet it is removeable without pain, hemorrhage, or hazard of any kind; the second of which circumstances, Mr. Pott can with strict truth affirm, he never met with when the disease was at all fit for the operation.

Of the benign kind of polypus fit for extraction, there are (says Mr. Pott) two sorts, whose principal difference from each other consists in their different origin or attachment. That which is most freely moveable within the nostril upon forcible respiration; which has been found to be most liable to change in size at different times and seasons; which has increased the most in the same space of time; which seems most limpid, and most freely yields lymph upon pressure; has its origin most commonly by a stalk or kind of peduncle, which is very small compared with the size of the polypus. The other, which, although plainly moveable, is much less so than the one just mentioned, which has been less liable to alteration from air and seasons, and which has been rather slow in arriving at a very troublesome size, is most frequently an elongation of the membrane covering one of the ossa spongiosa. These latter may be extracted with no kind of hazard, and with very little pain, and hemorrhage; but the former require the least force, and mostly come away entire; while the others often break, come away piecemeal, and stand in need of the repeated use of the forceps.

Mr. John Bel criticises the distinctions drawn by the preceding writer, and still adopted in the best schools of surgery: he says, that a polypus is never mild and never malignant; time, and the natural growth of the tumour, and the pressure it occasions within the soft and bony cells of the nostrils and jaws, must bring every polypus to one invariable form in its last and fatal stage. Polypus, he admits, is indeed a dreadful disease; but it becomes so by a slow progression, and advances by gradations easily characterized. Every polypus in its early stage is, according to this writer, a small moveable tumour, attended with a sneezing and watering of the eyes; swelling in moist weather; descending with the breath; but easily repressed with the point of the finger. It is void of pain, and not at all alarming; it may also be easily extracted, so as to clear for a time the passage for the breath. Yet this little tumour, simple as it may appear, is the germ of a very fatal and loathsome disease and this easy extraction often the very cause of its appearing in its most malignant form. The more easily it is extracted (says Mr. J. Bell), the more easily does it return; and, whether carelessly extracted, or altogther neglected, it soon returns. But when it does return, it has not really changed its nature; it has not ceased to be in itself mild; it is then to be feared, not from its malignity, but from its pressure among the delicate cells and membranes of the nose. It soon fills the nostrils, obstructs the breathing, and causes indescribable anxieties. The tears are obstructed, and the eyes become watery from the pressure on the lachrymal sac; the hearing is in like manner injured, by the pressure of the tumour against the mouth of the Eustachian tube; the voice is changed, and its resonance and tone entirely lost, by the sound no longer passing through the cells of the nose and face. The swallowing is in some degree affected by the soft palate being depressed by the tumour. The pains arising from such slow and irresistible pressure are unceasing. From the same pressure, the bones become carious, and the cells of the face and nose are destroyed by the slow growth of the swelling. It is not long before the tumour begins to project from the nostril in front, and over the arch of the palate behind. One nostril becomes widened and thickened; the nose is turned towards the opposite side of the face, and the whole countenance seems distorted. The root of the nose swells and becomes puffy, the features turnid and flabby, the face yellow, and the parts round the eye livid. The patient is affected with headaches, which seem to rend the bones asunder, and with perpetual stupor and dozing. The bones are now absorbed, and the membranes ulcerate; a foul and fetid matter, blackened with blood, is discharged from the nostrils, and excoriates them. The blood-vessels next give way, and sudden impetuous hemorrhages weaken the patient; the teeth fall from the sockets, and, through the empty sockets, a foul and fetid matter issues from the antrum.

Now the disease verges to its conclusion. The patient has terrible nights, and experiences a sense of suffocation. The repeated loss of blood renders him so weak that he cannot quit his bed for several days together; and when he does get up he is (to use Mr. Bell's words) pale as a spectre, his lips colourless, and his face like wax, yellow and transparent. He now suffers intolerable pain, while his saliva is continually dribbling from his mouth, and a fetid discharge from his nose. In this state he survives a few weeks; during the last days of his illness lying in a state of perpetual stupor, and dying lethargic. Mr. J. Bell afterward observes, that "if horrid symptoms could establish the fact of malignity, there is not to be found in all nosology a more malignant disease than this: but aneurism, though it destroys the thigh bone, the sternum, or the cranium, is not accounted malignant; neither is polypus malignant, though it destroys the cells of the face, and penetrates even through the ethmoid bone to the brain. These consequences result merely from pressure."—(*John Bell's Principles of Surgery, vol.* 3, *part* 1, *p.* 90—92.)

In April, 1817, there was a boy in St. Bartholomew's Hospital, only twelve years old, who fell a victim to the ravages of the largest and most disfiguring disease within the nose, which I ever had an opportunity of beholding. The tumour before death had expanded the upper part of the nose to an enormous size; while below, the left nostril was immensely enlarged. The distance between the eyes was extraordinary, being more than four inches. The left eye was affected with amaurosis, brought on by the pressure of the swelling; the right retained to the last the faculty of seeing. The tumour nearly covered the mouth, so that food could only be introduced with a spoon, and an examination of the state of the palate was impossible. About a fortnight before death, the legs became paralytic, and during the last week of the boy's existence, an incontinence of the urine and feces prevailed. On examination of the head after death, a good deal of the tumour was found to be of a cartilaginous consistence, and, what was most remarkable, a portion of it, which was as large as an orange, extended within the cranium, where it had annihilated the anterior lobe of the left hemisphere of the brain. Yet, notwithstanding this

effect, the boy was not comatose, nor insensible, till a few hours before his decease. All the surrounding bones had been more or less absorbed, and the place from which the excrescence first grew could not be determined.

Richter has denied the validity of the objections, urged by Pott against attempting to relieve the patient: and he declares, that neither the malignant nature of a polypus, its adhesions, immoveableness, ulcerations, nor disposition to hemorrhage, &c., are any just reason for leaving the disease to itself.—(See *Anfangsgr. der Wundarzn. b.* 1, *kap.* 21.) This declaration, however, at least with reference to any operation, is quite repugnant to the advice delivered by all the most experienced surgeons in England, who, in cases of decidedly malignant polypi, always restrict their interference to palliative means.

Mr. J. Bell refutes the common notions, that polypi may be caused by picking the nose, blowing it too forcibly, colds, and local injuries. He asserts that a polypus is not in general a local, solitary tumour: he has only found it so in three or four instances. Both nostrils are usually affected. He states, that no finger can reach that part of the nostril, where the root of the swelling is situated, as it is deep and high in the nostrils, towards the throat, and near the opening of the Eustachian tube. The finger cannot be introduced farther than the cartilaginous wing of the nose extends, and can hardly touch the anterior point of the lower spongy bone. The anterior and posterior chambers of the nostril are separated from each other by a narrow slit, which the finger can never pass, and which is divided in consequence of the projection of the lower spongy bone into two openings, one above, the other below. Through these the heads of the polypus project. These tangible parts of the tumour, however, are very distant from its root, which is in the highest and narrowest part of the nostril.—(See *p.* 103, 104.) Mr. J. Bell also says, that three or four polypi are often crowded together in one nostril, while more are formed or forming in the other.

He dwells upon the difficulty and impracticableness of tying the root of a polypus; and explains, that in all attempts to extirpate such tumours, the surgeon's aim should be to reach a point, nearly under the socket of the eye, in the deepest and highest part of the nostrils, and that instruments can only do good when introduced beyond the narrow cleft, formed by the projection of the spongy bone.—(*P.* 108.)

Though Mr. John Bell is probably right in his opinion, that polypi do not proceed from the several circumstances which have been above noticed, yet they are, in most instances, diseases of an entirely local nature. Certainly, in general, it is very difficult to describe what is the cause of a nasal polypus. Frequently, the patient is in other respects perfectly well; and after the removal of the tumour no new one makes its appearance. In this circumstance, it must originate from a local cause, though it is generally difficult to define what the nature of this is. Sometimes several catarrhal symptoms precede the polypus, and perhaps constitute its cause. It is possible, they may only be an effect of the same cause which gives birth to the tumour; but no doubt, they are sometimes the effect of the polypus itself. Sometimes, perhaps, a faulty state of the constitution really contributes to the disease; for several polypi frequently grow in both nostrils, and even in other situations, at the same time; are reproduced immediately after their removal; and the patient often has an unhealthy appearance.

There are four modes of extirpating nasal polypi: viz. extracting them with forceps, tying them with a ligature, cutting them out, and destroying them with caustic.

Extraction is the most common and proper method. It is performed with the ordinary polypus-forceps, the blades of which have holes in them, and are internally rather rough, in order that they may take hold of the tumour more firmly, and not easily slip off it. The front edge of each blade must not be too thin and sharp, lest with its fellow it should pinch off a portion of the polypus. The blades must necessarily have a certain breadth, for, when they are too small, they cannot properly take hold of and twist the tumour. When the handles are rather long, the instrument may be more firmly closed, and more conveniently twisted.

It is generally deemed of importance to take hold of the polypus with the forceps close to its root; and indeed, when this rule is observed, the whole of the polypus, together with its root, is commonly extracted, and there is less reason to apprehend hemorrhage, which is naturally more profuse when the polypus is broken at the thick, middle portion of its body. It is also a rule frequently easy of observance, especially when the polypus is not too large. With respect to common *fleshy* or *gelatinous polypi*, it should be remembered, that they usually originate from between the upper and lower turbinated bones, on the side of the antrum; and the best plan is, first to endeavour to ascertain with a probe the precise situation of the pedicle, which the forceps, guided by the probe, will then more readily grasp. Sir A. Cooper has never known an instance of the growth of a gelatinous polypus from the septum narium; a fact highly worthy of the practitioner's recollection. In many instances, the tumour is so large, and the nostril so completely occupied by it, that its root can neither be felt, nor taken hold of with forceps. The polypus should then be grasped as high as possible. The consequences are of two kinds. The tumour sometimes gives way at its root, though it be only taken hold of at its anterior part; and, in other cases, breaks where it is grasped, a portion being left behind, and a profuse hemorrhage ensuing. This is, however, void of danger, if the surgeon does not waste time in endeavouring to suppress the effusion of blood; but immediately introduces the forceps again, grasps the remnant piece, and extracts it. The most infallible method of diminishing the bleeding, is to extract what remains behind at its root. In this way a large polypus is frequently extracted, piecemeal, without any particular loss of blood.

After the polypus has been propelled as far forwards, into the nostrils as it can be, by blowing strongly through the nose, and the place of its root felt with a probe, its anterior part is to be taken hold of with a small pair of common forceps held in the left hand, and is to be drawn gradually and slowly out, to make room for the introduction of the polypus-forceps into the nostril. The more slowly we proceed in this manœuvre, the more the polypus is elongated, the narrower it becomes, the greater is the space in the nostril for the introduction of the polypus-forceps, and the higher can this instrument grasp the tumour. After the root of the polypus has been taken hold of with the polypus-forceps, or if this cannot be done, after the tumour has been grasped with the latter forceps as high as possible, it is to be twisted slowly round, and at the same time pulled outwards till it breaks. When the body of the polypus, and not the root, is grasped, it is a very important maxim, rather to twist the instrument than pull it, and thus, rather to writhe the polypus off than to drag it out. The longer and more slowly the polypus-forceps is twisted, the more the part where the excrescence separates is bruised, the less is the danger of hemorrhage, and the more certainly does the tumour break at its thinnest part or root. When the extraction is done with violence and celerity, only a piece is usually brought away, and we run hazard of occasioning a copious bleeding. Sir A. Cooper recommends tearing polypi from their attachment with a sudden jerk, as the most likely mode to bring away the whole of the root, and even a portion of the Schneiderian membrane and bone, so as to hinder a relapse: a piece of advice, however, which he seems to intend for cases in which the pedicle is grasped by the forceps, as it ought always to be if possible; but when circumstances oblige the surgeon to take hold of any other more accessible portion of the tumour, the rule of slowly and gradually twisting off the polypus, instead of using a sudden jerk, is what I consider the most likely method of extracting the tumour in a mass.

As soon as the polypus has given way, the surgeon is to examine whether any part remains behind. When the polypus is very narrow at the place where it has been broken, and the patient can breathe through the nose freely, there is reason to presume, that the polypus has given way at its root and that none continues behind. The finger, if it can be introduced, procures the most certain information; or the probe, when the finger for want of room cannot be employed. When a piece of the root is left, it is best to introduce the forceps again, under the guidance of the finger or probe, and thus pinch and twist off the remnant of the disease.

Some hemorrhage always follows the operation; and by many writers it is represented as perilous and alarming. But this is not the case in common fleshy gelati

nous polypi, which are not furnished with large vessels and are the instances in which the operation is most proper. Cases are met with, however, in which the bleeding is really serious; and therefore the surgeon should always furnish himself before the operation with the most effectual means for its suppression. The danger of hemorrhage may always be lessened, as was before mentioned, by slowly twisting the polypus at its root, in preference to pulling it directly out. When only a portion of the tumour has been extracted, the surest mode of stopping the effusion of blood is to extract the remaining part without delay. After the polypus has given way at its root, if the bleeding should still be profuse, ice-cold water or strong brandy may be sucked or injected into the nose. These applications mostly prove effectual. If the hemorrhage should still prevail, it may always be checked with certainty, how copious soever it may be, in the following manner. Roll a considerable piece of lint as fast as possible round the extremity of a probe; wet it completely through with a strong solution of the sulphate of zinc; introduce it into the nostril, and press it as strongly as possible against the part whence the blood issues. When the nostril is very much dilated, the fingers may be used for this purpose, with more advantage than the probe. The point from which the blood is effused may easily be ascertained by pressing the finger on various points. As soon as the blood ceases to flow, we may conclude that the finger is on the situation of the hemorrhage.

When this method fails, a piece of catgut may be introduced into the nostril, and, by means of a pair of forceps, be brought out of the mouth. A roll of lint is then to be attached to it, and drawn through the mouth into the nose; thus the posterior aperture of the nostril may be stopped up. Then the nostril in front is to be filled with lint.

Sometimes the greatest part of the polypus extends backwards, hanging down behind the palatum molle towards the pharynx. If there should be but little of the polypus visible in the nostril, its extraction must be performed backwards, in the throat. This is usually done with a pair of curved polypus-forceps, which are to be introduced through the mouth, in order to seize and tear off the tumour as high as possible above the soft palate. Care must be taken not to irritate the root of the tongue, or else a vomiting is produced which disturbs the operation. When the polypus cannot be properly taken hold of, some surgeons divide the soft palate. But this can hardly ever be necessary. As by this mode, the polypus is not twisted, but pulled away, the hemorrhage is, in general, rather copious. If a fragment of the tumour should remain behind, it may commonly be extracted through the nose.

Some recommend for the extraction of polypi in the throat, a ring, consisting of two semicircular portions, with a kind of groove externally, which are capable of being opened and shut, by being fixed on the ends of an instrument, constructed like forceps. A ligature is to be placed round the ring, and its end is to be brought to the handle of the instrument, and held with it in the hand. The instrument is to be introduced into the mouth, under the polypus, and expanded as much as the size of the tumour requires. Its ring is then to be carried upwards, over the polypus, so as to embrace it; and afterward is to be shut, whereby the noose, after being carried upwards is disengaged from the ring. The noose is to be pushed as high as possible over the tumour by means of forceps, and the extremity of the packthread is then to be drawn, so as to apply the noose tightly round the polypus. When this is done, the ring of the instrument is to be turned round, firmly closed, and placed in front of the polypus, on the noose, in such a way that the packthread is to lie between two little pegs, made for the purpose, at the ends of the ring. On drawing the packthread firmly, and pressing the instrument at the same time downwards, so as to make it act like a lever, the polypus, in general, easily breaks. Another peg projects in the direction of the ring, so as to prevent the ligature from insinuating itself within the circle.—(See *Theden's Bemerk. part 2; and plate 6, fig. 1, in Richter's Anfangsgr.*)

This instrument is at present rarely or never employed, and Richter, who sets down its use as attended with difficulty, recommends the extraction to be performed with forceps through the mouth. When the tumour cannot be drawn completely out without considerable force, a spatula is to be introduced into the mouth, and to be carried as high as possible behind the polypus, in order to press it down towards the root of the tongue. When the tumour is now forcibly pulled out with the forceps, it usually gives way.

When the polypus is situated partly in the throat and partly in the nostril, it admits of being extracted in the same way, through the mouth; but its anterior part often continues attached, and must afterward be separately removed through the nostril. It is also frequently advisable to twist off the anterior portion of the polypus first, by which the mass in the throat is often rendered so loose, that it can be easily extracted Whenever it is conjectured that the polypus will come away in two pieces, it is always preferable first to extract the part in the nostril, and afterward that in the throat; because the separation of the last is constantly productive of more bleeding than the removal of the first. Sometimes the following plan succeeds in detaching the whole polypus at once. Both the part in the nostril, and that in the throat are to be firmly taken hold of with forceps, and drawn at first gently, and then more forcibly, backwards and forwards. By such repeated movements, the root is not unfrequently broken, and the whole polypus brought away from the mouth.

Frequently the polypus grows again. Policy requires that the patient should be apprized of this beforehand. Some of the root remaining behind may often be a cause of the relapse. Hence, after the operation, the surgeon should carefully examine the part at which the root of the polypus was situated, and separate and twist off most diligently with the forceps any fragments that may still continue attached. Or if, in the operation itself, the root can be grasped with the forceps, it may be torn away with a sudden jerk, as recommended by Sir A. Cooper, for the express purpose of bringing away with the root the portion of Schneiderian membrane and even bone from which the tumour originates, so as to prevent its growing again. The recurrence of the disease, however, may arise from other causes. The tumour is occasionally reproduced after it has been extracted in the most complete manner; and, doubtless, this circumstance is sometimes owing to the continued agency of constitutional causes, which so often remain undiscovered and unremoved. Sometimes also, the recurrence of the disease is owing to a local morbid affection of the Schneiderian membrane, or of the bones situated beneath the root of the polypus. Richter, in this case, approves of the cautery; but few English surgeons will coincide with him. The polypus, sometimes observed subsequently to the operation, is frequently not, in fact, a new substance, but only a part of the original tumour, not previously noticed by the surgeon. Sometimes it occurs, that a smaller and a larger polypus are found in the nose at the same time. The larger one is extracted while the other remains undiscovered; and, when it has increased in magnitude, it is apt to be mistaken for a reproduction of the one previously extirpated.—(See *Anfangsgr. der Wundarzn. b. 1, k. 21.*)

Ligature. The hemorrhage that has occasionally arisen from attempts to extract certain polypi, and more especially from the imperfect removal of them in this manner, led to the proposal of extirpating them with a ligature. The plan is, to tie the root of the tumour, by which means the polypus is thrown into the state of sphacelus, and at length becomes detached. Many instruments have been invented for this purpose, but Levret's double cannula seems to be the best. Through this a silver wire is to be introduced, so as to form a noose at the upper end of the instrument, proportioned in size to the anterior part of the tumour, situated in the nostril. The two ends of the wire are to hang out of the two lower apertures of the double cannula: and one of them is to be fastened to a small ring on its own side of the instrument. The other is to remain loose. The wire must be made of the purest silver, and ought to be as flexible as possible, that it may not readily break. It must also not be too thin, lest it cut through the root of the polypus. The cannula is to be somewhat less than five inches long. By the assistance of this cannula, the noose is to be introduced into the nose, and put round the polypus. But as the cannula, which is usually constructed of silver, is straight and inflexible, while the inner surface of the nostril is preternaturally arched, especially when much distended by the polypus, its introduction must be attended with considerable

difficulty. In fact, it can seldom be introduced as deeply as the root of the polypus.

The noose is to be applied in the following manner. The polypus is to be taken hold of with the forceps, and drawn a little out of the nose. The noose is then to be carried over the forceps and polypus, into the nostril. In order to carry it as high as possible, it is necessary not to push the cannula straight forwards into the nose, but to move it from one side of the polypus to the other. The more deeply the instrument has entered the nose, the more of the loose end of the wire must be drawn out of the lower aperture of the cannula, so as to contract the noose, which otherwise might stop in the nostril, and not be carried sufficiently high. The elasticity of the silver wire tends to raise it over the polypus, and hence it is more easy of application than a more flaccid kind of ligature. When there is cause to conclude, that the polypus is complicated with adhesions, they must be previously broken in the way already mentioned.

As soon as the noose has been introduced as deeply as possible, the loose extremity of the wire is to be drawn out of the lower aperture of the cannula, and rolled round the ring on that side of the instrument. Thus the root of the polypus is constricted. The wire must not be pulled too forcibly, nor yet too feebly. In the first circumstance, it readily cuts through the root of the polypus; in the second, great tumefaction of the excrescence, and many inconveniences arise, which a tenser state of the wire prevents. As the noose gradually makes a furrow, where it surrounds the polypus, it grows slack after a short time, and no longer constricts the tumour. One end of the wire, therefore, is to be daily unfastened, and drawn more tightly. The more tense it is kept, the sooner the separation of the polypus is brought about. Hence, when it is particularly indicated to produce a speedy detachment of the polypus, the wire should be tightened at least once a day.

In this manner the cannula is to remain in the nose, until the noose is detached together with the polypus. There is another method of tying the tumour, without leaving the cannula in the nose. After the noose has been introduced as far as possible into the nostril, the two ends of the wire are to be twisted round the two rings, and the cannula is to be turned round a couple of times. The wire is then to be unfastened from the rings, and the cannula withdrawn. In this way, the noose is made to embrace the polypus, round which it remains firmly applied. When it is wished to produce a greater constriction, the cannula is again introduced into the nose, the ends of the wire fastened to the rings, and the instrument turned round again; after which it is taken away as before.

When the tumour has begun to slough, and a fetid discharge has commenced, a solution of alum, or of chloride of lime or soda, should be repeatedly injected into the nostril for the sake of cleanliness; and immediately the dead mass is sufficiently loose it should be removed.

Although the ligature has been very much praised by some of the moderns, it is attended with so many difficulties, that, in the majority of cases, the use of forceps is infinitely preferable. Hemorrhage is the only inconvenience for which extraction is abandoned for the employment of the ligature. But this is much less dangerous than is represented. The inconveniences of the ligature are far more serious and numerous. The cure by the ligature is always accomplished with much less expedition than that by extraction. When the polypus is of such a size as to occupy the whole of the nostril, it is generally impracticable to introduce the noose to a sufficient depth. The figure of the polypus renders it almost impossible to tie its root; for, commonly, the tumour expands very much before and behind, and the wire must be brought over the posterior part of the polypus ere it can be applied to its root. In general also, the noose only includes the front part of the polypus, while the root and back portion remain untied, and consequently are not destroyed.

As soon as the noose is drawn tight, not only the polypus inflames, but the whole extent of the Schneiderian membrane. The pain and inflammation frequently extend even to distant parts, as the throat, eyes, &c., attended with a great deal of fever.

When the polypus is tied, it swells very much, and all the complaints which it previously caused are exasperated. But, in particular, the part situated in the throat sometimes obstructs deglutition and respiration in such a degree, that prompt relief becomes necessary; and one of the best plans for affording it is, to make a few punctures in the tumour.

The wire sometimes breaks off close to the lower aperture of the cannula, in consequence of being twisted so much, and thus the progress of the cure is interrupted. A new wire may be introduced; but it is difficult to apply it exactly in the situation of the other. A fresh place is commonly tied, which is almost the same thing as commencing the cure anew.

After enumerating so many inconveniences of the ligature, as a means of curing nasal polypi, I shall only remark, that it is not surprising, that the plan should now be hardly ever adopted by any good surgeons in this country. Among other authorities, I may cite that of Sir A. Cooper, who has tried the ligature unavailingly, and pronounces its application to these cases to be decidedly unadvisable.

Caustics. The cautery, formerly recommended for the cure of the polypus nasi, is now entirely rejected, and indeed, in the manner it was customary to use it, little good could be done. It was applied to the anterior surface of the tumour in the nostril, and its employment was repeated every time the slough separated. Its operation could naturally be but of small extent, as it only came into contact with a trivial portion of the polypus. Its irritation augmented the determination of blood to the excrescence, and accelerated its growth; while as much of the tumour was reproduced, ere the slough separated, as was destroyed; and the design of completely extirpating the disease in this way seldom or never proved successful.

There are some nasal polypi much disposed to profuse bleeding. Touching them in the gentlest manner, and every trivial concussion of the body, give rise to hemorrhage. The patient is exceedingly debilitated by repeated loss of blood; his countenance is pallid; his feet swollen; he is affected with hectic fever; and faints whenever any considerable bleeding arises. Doubtless, extraction in this case is a very precarious method, as the patient is so circumstanced, that any copious effusion of blood must be highly perilous. Sometimes the polypus is at the same time so large, and the nostril so completely occupied and distended, that it is impossible to apply a ligature. Such is the only case in which even Richter sanctions the use of the cautery.

In employing the cautery (says the latter author), the object is not to effect, by its direct agency, a sudden destruction of the polypus; but to excite such an inflammation and suppuration of the whole of it, as shall lead to this event. To fulfil this purpose, a common trocar, three inches long, may be used. The cannula ought to be two inches shorter than the trocar whereby the latter may protrude from it so far; and it should be constructed with a handle. The cannula should be made wider than it is in common, so as to allow the trocar to be introduced and withdrawn with facility. It is to be wrapped round with a piece of wet linen, and applied to the polypus. The red-hot trocar is then to be pushed into the tumour as far as the cannula will allow, which is, of course, two inches.

When the patient entertains a dread of the actual cautery, Richter recommends the introduction of a tent of the emplastrum cantharidum, or a tent smeared with butter of antimony, into the puncture of the unheated trocar, and as soon as suppuration has taken place, emollient and detergent lotions are to be injected. —(*Richter's Anfangsgr.*) In England, actual and potential cauteries are never used for the destruction of common nasal polypi; but red projections, not of a polypous nature, sometimes noticed within the nostrils of children, Sir A. Cooper cures by touching them with a bougie armed with the argentum nitratum. The cysts of the hydatid polypus the same gentleman also destroys, by applying the muriate of antimony to them with a camel-hair pencil.

Excision. In the treatment of the polypus, the use of cutting instruments has always been reprobated, because they usually occasion a profuse hemorrhage, and can hardly ever be passed without mischief to a sufficient depth into the nose to divide the root of the tumour. Yet there are instances in which their use might be productive of advantage. The anterior part of the polypus, situated in the nostril, is sometimes so

thick and hard, that it is utterly impracticable to introduce the forceps for the performance of extraction, or the cannula for the application of the ligature. In such a case, it might be a judicious step to cut off the front of the polypus, with a sharp instrument of a suitable shape, in order to make room for the use of the ligature or forceps.

Sir A. Cooper sometimes removes polypi by dividing their pedicle with a pair of probe-pointed scissors; but his experience has taught him that the disease, when thus extirpated, is more likely to return than when cured by extraction. When a polypus is very large, and the pedicle grows from the side of the antrum, he also sometimes cuts through the root with a pair of curved scissors, and presses down the polypus at the back of the mouth with his finger, from over the velum pendulum palati, and thus removes it. He has never seen danger or difficulty arise from the plan, but, on the contrary, has known it answer in several instances, in which the forceps had been employed through the nostrils in vain.—(*Lectures, &c. vol.* 2, *p.* 352.)

Mr. Whately, after failing in several attempts to extract and tie a considerable polypus of the nose, succeeded in cutting it out. He used "a narrow, straight bistoury, with a probe point, having a sheath fixed upon its edge, by a screw put into a hole in the handle. An eye was made at its point, to receive one end of a thread intended to be passed round the polypus, for the purpose of directing the knife to the extremity of the tumour. There was also a contrivance by which the knife could be unsheathed at its extremity, the length of three-quarters of an inch. This was done by means of the screw, which might be fixed in another hole, by drawing back the sheath. By exposing such a length of edge only, the anterior parts of the nose were defended from the danger of being wounded." Whoever wishes a particular account of the manner of using the instrument, must consult Mr. Whately's *Cases of two extraordinary Polypi, &c.* 1805.

In the polypus which arises from a relaxation of the Schneiderian membrane, external astringent applications may be first tried; such as ice-cold water, solutions of acetate of lead, alum, muriate of ammonia, &c. These remedies (says Richter) commonly lessen it, and frequently, when it is not very large, accomplish its entire removal. If this should not happen, there is no reason against putting a ligature round it. Here, also, we may venture to employ a cutting instrument, if it be in our power to do so; which, as far as my experience goes, will very rarely be the case. But the practice of extraction is here prohibited. A strong solution of alum, introduced into the nostril with a dossil of lint, will also remove the hydatid polypus of young persons, as Sir Astley Cooper has explained. These polypi he compares to wet bladders hanging within the nose: they are not attended with pain, though with the inconvenience of obstruction. When pressed with the forceps they burst, and discharge a fluid resembling mucus. The nose may be frequently cleared of them by instruments; but they are always regenerated. Whether astringents will cure them permanently, he cannot say positively.—(*Lectures, &c. vol.* 2, *p.* 353.)

POLYPI OF THE UTERUS.

Polypi of the uterus are of three kinds, in respect of situation: they grow either from the fundus, the inside of the cervix, or the lower edge of the os uteri. The first case is the most frequent; the last the most uncommon. Polypi of the uterus are of a pyriform shape, and have a thin pedicle. They are almost invariably of that species which is denominated fleshy, hardly ever being scirrhous, cancerous, or ulcerated. Sometimes they contain a cavity filled with fluid, resembling mucus or lymph. They originate under the mucous membrane, which still covers them; a circumstance in which they differ from sarcoma and steatoma of the uterus, which are situated in its substance, or on its external surface.

A polypus of the fundus uteri is very difficult to detect in its incipient state. While small, it produces not the smallest perceptible change in the organs of generation. As it enlarges, it distends the uterus, and often excites a suspicion of pregnancy, which, however, an attentive inquiry soon dispels. The swelling of the abdomen does not take place in the degree and space of time which it does in pregnancy, the menstrual discharge generally continues, though often irregular and profuse; the breasts do not become full; and, in the progress of the case, no motion is to be felt. While the polypus lies in the uterus, its growth is slow. At this early period, it frequently occasions profuse bleeding. Women afflicted with the disease are seldom pregnant, and when they are so, a miscarriage mostly follows. However, they sometimes hold out till the end of the regular time, and the labour is easy and safe. Levret, Bach, and Jörg have recorded cases, in which the fœtus reached its full term. In Bach's case, the placenta was attached to the polypus; a fact, I should think, quite sufficient to dispel all doubt about the vascularity of uterine polypi.

In some instances, however, the case is more perplexing; the catamenia disappear, and other marks of pregnancy are present, such as nausea, vomiting, and enlargement of the breasts. By degrees the uterus, and sometimes even the abdomen, is distended. The cervical portion of the uterus is shortened, and becomes thick and tumid, but, instead of the softness peculiar to pregnancy, it retains a solid feel. A sensation of weight about the genitals, and of bearing down, is also experienced: frequently the bowels are constipated, and there is difficulty in voiding the urine. —(*Mayer, De Polypis Uteri, Berolini*, 1821.)

As the polypus increases, it expands the os uteri, and at length protrudes into the vagina. This change happens sooner or later, according as the polypus is attached to the cervix or the fundus uteri; for, in the first case, the polypus generally protrudes when it has attained the size of a finger, but, in the second, it may remain in the uterus several years, and be as large as a child's head before its protrusion commences. The dilatation of the os uteri by the swelling is also mostly attended with a discharge of mucus mixed with blood, and sometimes with dangerously profuse bleeding. The protrusion happens either suddenly from an accidental concussion of the body, or slowly and gradually, attended with pains similar to those of labour. As soon as it has arrived in the vagina, and is no longer confined and compressed by the uterus, it begins to grow more rapidly, and gives rise to far more troublesome complaints; for it presses the bladder and rectum, and seriously disturbs the evacuation of the urine and feces. But, in particular, it causes repeated and profuse hemorrhages, which weaken the patient exceedingly, and often bring her to the brink of the grave. The root of the polypus is situated in the os uteri, and is there so compressed, that the blood in the tumour is prevented from returning through the veins; consequently, all the vessels become turgid, and the above effusions of blood are the result. Though they generally cease spontaneously, the least circumstances cause their recurrence; such as slight concussions of the body in riding, walking, &c. In the mean while, a quantity of mucous and aqueous fluid is voided, by which the patient's strength is more reduced; and at length hectic fever and anasarca come on. The polypus, the source of the bloody and mucous discharge, as well as of all the patient's illness, is frequently misunderstood, and the case is really attended with great danger, from its nature not being comprehended by the practitioner: so necessary is it, in cases of preternatural discharge from the uterus, always to examine with the finger, *per vaginam*.

At length, after the polypus has been some time in the vagina, it begins to protrude externally. This happens gradually or suddenly from some effort or concussion of the body. Additional grievances are now excited. As the polypus cannot descend so low, without dragging the fundus of the uterus downwards with it, and occasioning a prolapsus of this organ, the patient, in walking or standing, commonly experiences a very painful sense of dragging or stretching in the pelvis. As the bladder and ureters are also forced into a deranged position, the evacuation of the urine is more or less disturbed, or rendered difficult. Lastly, the dribbling of the urine over the polypus, and the friction which the part accidentally suffers, frequently cause it to inflame, and become painful and ulcerated.

A polypus situated in the vagina, or protruding from it externally, may easily be mistaken for a prolapsus uteri; an error, which, though not difficult to avoid when a careful examination is made, may have very perilous consequences. The polypus is softer and less

sensible than the uterus in the state of a prolapsus. The imperfect prolapsus uteri, in which this viscus is not turned inside out, is betrayed by the os tincæ, at the lower part of which it is plainly perceptible. In this situation, the polypus may occasionally have a depression, resembling the mouth of the womb, but easy of discrimination from it. A probe can be passed deeply into the os uteri; but not so into this other opening. The polypus resembles an inverted pear; that is, it is thickest below, and becomes gradually thinner upwards. The above species of the prolapsus uteri is thinnest below, and gradually increases in width upwards. The fallen uterus may easily be pressed back, and when it is so, the patient experiences relief. The polypus does not admit of being pressed back, and, during an attempt to do this, the patient is put to much inconvenience. A probe may be introduced by the side of the polypus deeply to the fundus uteri. When passed by the side of the fallen uterus, it is very soon stopped at the upper part of the vagina, which has sunk down with the cervix of this organ.

A polypus, protruding externally from the vagina, may be much more easily distinguished from a perfect prolapsus uteri, without inversion. The os uteri at once characterizes the uterus, as it can not only be felt, but seen. A probe may be passed deeply into the vagina, along the side of the polypus; but not so by the side of the uterus, for reasons easy of comprehension. The figure of the tumour, and the state of the patient, on an effort being made to reduce the protruded part, also betray its real nature.

With the exception of a few examples, in which an inversion of the uterus is caused by the descent of a large polypus into the vagina, it happens only in women who have been recently delivered, and has generally been preceded by a very rapid delivery, or the use of too much violence in the extraction of the placenta. While the inverted uterus lies in the vagina, its shape is broad above and narrow below; whereas the polypus is thin above, and broad below. Hence, in cases of very large polypi in the vagina, the os uteri is but little dilated; while it is extremely distended by the incomplete descent of the inverted uterus itself. Here, likewise, the reduction of the part is attended with relief; while every effort to push back a polypus causes an aggravation of all the complaints.

When the inverted uterus hangs out of the vagina, its figure, like that of the polypus, is thin upwards and broad downwards; and like the latter tumour, has no aperture at its lowest part. An attentive observer, however, will easily avoid a mistake. The inverted uterus includes a circular fold at its upper part, next to the orifice of the vagina. This fold is nothing less than the os uteri itself, through which the body of this viscus has descended. There is nothing of this kind to be felt in cases of polypi. By the side of a polypus the finger or probe may be passed deeply into the vagina; but not so by the side of the uterus. The root of the polypus is firm and hard to the touch; the upper thin part of the uterus, which is hollow, has a soft, flabby feel. Useful light is also generally thrown on the case by the common occasional cause of prolapsus uteri with inversion. The symptoms of a complete inversion are a red, fleshy tumour, as large as a fist or a child's head, protruding from the genitals, with violent pains, and profuse hemorrhage, often causing syncope, convulsions, and death. The uterus feels rough, elastic, and painful: the uterine tumour ordinarily felt above the pubes is wanting; the inversion, though with difficulty, may be returned. On the other hand, a polypus is insensible, hard, and smooth; it may be returned into the vagina with considerable pain, but is immediately expelled again. On the inverted uterus the mouths of the bleeding vessels and the placenta, or place of its insertion, may be seen.—(*Mayer, see Quarterly Journ. of Foreign Med. vol.* 4, *p.* 476.) However, in particular cases the diagnosis is much more difficult, and the observations of a modern writer fully prove, that it is always difficult and perhaps sometimes impossible to distinguish a *partial* and *chronic* inversion of the uterus from a polypus.—(*W Newnham on Inversio Uteri, with the History of the successful Extirpation of that Organ, during the Chronic Stage of the Disease, p.* 82, *&c.* 8*vo. Lond.* 1818: *also, First Lines of the Practice of Surgery, vol.* 2, *p.* 317.)

Under Professor Siebold, however, Mayer has had several opportunities of seeing *chronic incomplete inversion*, and he mentions the following circumstances, in addition to some others already specified, as forming the diagnosis between it and polypus. Polypus not unfrequently occurs in women who are barren; inversion in those who have borne children The symptoms of polypus, commencing with disorder of the menses, and frequently with their suppression, increase constantly, and when the tumour is passing into the vagina, are accompanied with pains like those of labour. On the contrary, the symptoms of inversion date their origin from the time of delivery: menorrhagia, unusually violent pains, and excess of the lochia in quantity and duration, succeeding to a very rapid labour, or to a rough and violent extraction of the placenta. In cases of polypus, a discharge of mucous fluids, mixed with blood and membranous fragments, is always present, occasionally alternating with copious hemorrhage; while, in examples of inversion, there is, in fact, an excess of the menses; the hemorrhage appears every second or third week, is very copious for some days, and is succeeded by a serous, thin discharge, as clear as spring water. A polypus is altogether insensible; but the uterus, however its sensibility may be lessened by the duration of the disease, the effect of astringent applications, &c., is always capable of sensation when gently scratched with the nail.—(See *Mayer's Work, and the Quarterly Journ. of Foreign Med. &c. vol.* 4, *p.* 477.)

In cases of uterine polypi, situated either on the inside of the cervix, or at the margin of the os uteri, the disease is, as it were, from its commencement, in the vagina, and the tumour, when large, produces all the complaints attending polypi of the first kind, except frequent profuse bleedings. These seldom occur, and when they do, are slight, because the root of the polypus suffers no constriction in the os uteri. The discharge of mucus, however, is more profuse than when the polypus is attached to the fundus uteri. As the tumour descends out of the vagina, it occasions a prolapsus uteri without inversion, in addition to the other inconveniences. Cases sometimes occur, in which polypi of the uterus are detached by sphacelation, and a cure is thus spontaneously produced. These are facts well calculated to obviate the doubts entertained by Mayer respecting the vascularity of tumours. Indeed, the mode of cure by ligature can only be explained by its interrupting the supply of blood to them.

With regard to the treatment of uterine polypi, no attempt can be made to extirpate them until the os uteri is sufficiently dilated to permit the application of a ligature or the practice of excision. In the mean time, the attacks of hemorrhage are to be checked by strict repose; the supine posture; small doses of opium: mineral acids, particularly the phosphoric; alum; and cold injections of vinegar. When these means fail, however, and the hemorrhage endangers life, the os uteri should be artificially dilated and the polypus immediately removed. Constipation and retention of urine may also sometimes require special attention, before the os uteri has become dilated enough for the extirpation of the tumour.—(*Mayer.*)

According to the latter experienced practitioner, the best period for undertaking either to tie or cut away a polypus of the uterus, is soon after the menses or after hemorrhage, the genitals being then lax and the flow of blood to them diminished.

Experience proves that uterine polypi, when once extirpated, have not that propensity to be reproduced which those of the nose have. Here, for obvious reasons, extraction is not the right practice.

For the extirpation of polypi of the uterus, all the methods mentioned for the eradication of nasal polypi have been proposed: but modern practitioners hardly ever employ more than two, viz. the ligature and excision.

The ligature is generally the most proper means for extirpating uterine polypi, and is here much more easy of application than in the nose. Large as the polypus may be, there is always abundance of room for the introduction of the necessary instruments. The polypus of the uterus has commonly a thinner pedicle than that of the nose; hence its cure by the ligature is more expeditious; and on account of the greater room and more yielding nature of the parts, the swelling of the tumour, after the ligature is applied, produces less inconvenience than in the same mode of treatment of nasal polypi. The inconveniences which do arise are

easy of removal; for instance, the retention of urine may be relieved by the catheter; costiveness by glysters &c. Uterine polypi are also less sensible than those of the nose, and hence less pain and fever follow the application of a ligature to them. The fetid matter, formed as soon as the polypus sphacelates, has a free vent out, and may easily be washed away by injections.

That the polypus cannot be tied while it lies in the uterus, is easily comprehensible. But immediately it has descended into the vagina, the operation may be undertaken, and may be performed with the same kind of double cannula as is employed in the nose. However, here it is extremely requisite that the cannula should be rather longer than that already described, and somewhat curved. But as the silver wire sometimes breaks, two other very convenient instruments have been invented.

The first is Levret's instrument. It consists of two silver cannulæ which are curved in such a manner, and so united by a joint that they are shaped like a pair of forceps. After introducing a ligature through the two tubes, so that its ends hang out of their lower apertures, the instrument is to be shut and passed upwards into the vagina, over the polypus, on whichever side seems most convenient. Then it is to be opened, and the polypus is to be pushed through the two branches of the instrument, which is to be brought over the opposite side of the tumour. In doing this, the ligature becomes applied round the root of the polypus, and forms a noose. The extremities of the ligature are next drawn as tightly as possible out of the lower openings of the cannulæ, and tied first in a surgical knot, and then in a slip-knot. The instrument is then shut, and the ligature constricts the root of the polypus. Afterward it is to be tightened daily until the tumour separates.

Another instrument described by Nissen, *De Polypis Uteri* (see *Richter's Chir. Bibl. b.* 9, *s.* 613), is sometimes preferred. It consists of two silver tubes, twelve inches in length, and as thick as an ordinary writing-pen. Both are curved about as much as the os sacrum; but as they are made of pure silver, the curvature may easily be increased or diminished according to circumstances. Through each of the cannulæ a strong ligature is to be passed, so that its ends hang out of the lower apertures, while its middle portion forms a noose between the upper apertures of the cannulæ.

The tubes are to be kept together until they have been introduced into the vagina as far as the root of the polypus. One is then to be held fast, while the other is to be carried round the tumour, or to the opposite side of the cannula that remains stationary. Thus the ligature becomes applied round the root of the polypus. After introducing the finger into the vagina, to ascertain that the ligature lies in its proper situation, its ends are to be drawn through a small double cannula, which is only one-third of an inch long, but so wide that it can be pushed over both the tubes a certain way with the finger and the upper end of the long cannulæ, with the aid of a sort of long probe with a forked extremity. Then a third double cannula, through which the ends of the ligatures have likewise been passed, and the width of which is sufficient, is to be pushed over the lower ends of the long cannulæ so as to unite them. The ligatures are next to be drawn tight in the ordinary way, and fastened to the rings. The management of this instrument is so easy as to need no farther explanation.

Besides the above instruments, many others have been devised and recommended for tying polypi of the uterus. In particular, one invented by Desault, and another, which is preferred by Mayer, claim the attention of such surgeons as wish to be informed of others.

The ligature sometimes brings on acute symptoms of an inflammatory or spasmodic kind. The former require antiphlogistic treatment. Sometimes fever arises, and the polypus becomes exceedingly painful: in this case venesection is necessary. Spasmodic symptoms require the exhibition of opium. When this is ineffectual, and the symptoms are severe, it may be proper to slacken the ligature a little. As the polypus at first always swells, it produces great pressure on the adjacent parts. For this reason it is generally necessary, for the first few days, to draw off the urine with the catheter, and to open the bowels with clysters. Sometimes hemorrhage takes place. This may generally be suppressed by the means already specified; but when they prove ineffectual, the ligature must be tightened.

During the sphacelation and separation of the polypus, the frequent use of injections will be necessary for the sake of cleanliness, and, as soon as the mass is loose enough, it should be removed with a suitable pair of forceps.

Richter, in common with most practical writers, disapproves of cutting instruments as generally improper for polypi of the uterus, because likely to injure the vagina and occasion a dangerous hemorrhage. He sanctions the use of the knife, however, when the polypus has a ligamentous pedicle, and cannot be made to separate with a ligature. In this instance, he says, the surgeon may either cut off the polypus closely to its root in the vagina; or he may first draw it gradually downwards out of this situation, and then remove it: perhaps the first object might be performed with a sharp hook, somewhat curved at its side, and similar to what is used for tearing the fœtus piecemeal in the uterus; or with what seems better, a pair of long, curved, blunt-pointed scissors. The last object may be accomplished with an instrument resembling Smellie's midwifery-forceps, which is to be introduced into the vagina in the ordinary way. The polypus is then to be taken hold of, and very gradually drawn so far out of the vagina, that its pedicle may be divided with a knife. This is, indeed, not done without pain, and a forcible inversion of the uterus; but it has been successfully practised.—(See *Herbiniaux, Parallèle des differens Instrumens pour la Ligature des Polypes.*)

When a polypus, with a pedicle attached to the fundus uteri, suddenly falls downwards, it occasions a sudden inversion of this viscus. In order to relieve, as speedily as possible, the great pain and danger of this case, the surgeon must tie the root of the polypus as soon and as firmly as he can, and pass the ligature, by means of a needle, through the pedicle, before the place where it is tied, allowing the ends afterward to hang down for some length. Then the polypus is to be amputated below the ligature, and the uterus immediately reduced.

Siebold and Mayer, of Berlin, only approve of the ligature in two cases: 1st, when an artery can be felt pulsating in the neck of the polypus; 2dly, when the neck of the tumour is so thick that it probably contains large vessels. In all other examples they prefer excision, on the ground of the difficulty of applying a ligature, and because, when applied, the symptoms are apt to be more severe, and the annoyance greater than after excision. They operate with round-pointed scissors, curved like a Roman S both in the blades and handles, and from 9 to 10½ French inches in length The division of the neck of the tumour is to be effected not all at once, but by repeated strokes of the instrument. In Mayer's work six cases are related in which polypi of the uterus were thus successfully removed by Siebold and himself.

Fleshy excrescences occasionally form in the vagina, some of which have a broad basis, and others a thin pedicle. The last merit the appellation of polypi. Their existence is easily ascertained by the touch. By making pressure on the bladder and rectum, they occasion several impediments to the evacuation of the urine and feces. They may be conveniently tied by means of the double cannula. Should the polypus be situated at the lower part of the vagina, this instrument would not be required. The ligature might be applied with the hand, and the tumour cut off below the constricted part.

A polypus in the œsophagus renders deglutition difficult: and when of large size, puts an entire stop to it. When an inclination to vomit is excited by irritating the throat with the finger or a feather, the polypus, if situated towards the upper part of the tube, ascends into the mouth, so as to become visible. But as it impedes respiration during its residence in the mouth, the patient is soon necessitated, as it were, to swallow it again. When it is situated far down the œsophagus, of course it cannot be brought into the mouth, and is very difficult to detect. The difficulty of swallowing, its only symptom, may result from other causes. In this case it is also incurable; for it is impossible to take hold of it with instruments. An operation can only be practised when the polypus is situated at the upper part of the œsophagus. The

tumour cannot be extracted; and the tying of it is difficult. Sir Astley Cooper, however, has succeeded with a ligature in two examples.—(*Lectures, &c. vol.* 2, *p.* 356.)

Polypi in the rectum may be tied with the aid of the cannulæ. Excrescences in the meatus auditorius externus, resembling polypi, have been successfully extirpated by extraction, or rather by twisting them off.

PORRIGO, TINEA CAPITIS (called also *Ringworm of the Scalp, Scald-head, &c.*), is, according to Dr. Bateman's excellent account of the subject, a contagious disease, principally characterized by an eruption of the pustules denominated *favi* and *achores*. The *achor* is defined to be a small acuminated pustule, containing a straw-coloured matter, which has the appearance and nearly the consistence of honey, and is succeeded by a thin brown or yellowish scab. The *favus* is larger, flatter, and not acuminated, and contains a more viscid matter; its base, which is often irregular, is slightly inflamed; and it is succeeded by a yellow, semi-transparent and sometimes cellular scab, like a honey-comb; whence it has obtained its name. —(See *Bateman's Synopsis of Cutaneous Diseases, p.* xxiv. *and* 159, *edit.* 3.)

This intelligent physician has noticed six species of porrigo, of which my limits will allow me to give only a very abridged description.

1. The *porrigo larvalis*, or *crusta lactea* of authors, begins with an eruption of numerous minute whitish *achores*, upon a red surface. These pustules soon break, and discharge a viscid fluid, which concretes into thin yellowish or greenish scabs. The disease increases in extent, and the scabs become thicker and larger, until the forehead and cheeks, even the whole face, excepting the eyelids and nose, become enveloped as it were in a mask, whence the epithet *larvalis*. Small patches of the disease sometimes appear about the neck and breast, and on the extremities; and the ears and scalp are usually affected in the progress of the case. The infant suffers more or less from the itching and irritation. When the discharge is copious and acrid, Dr. Bateman recommends the part to be washed two or three times a day with tepid milk and water, and the application of the unguentum zinci alone, or mixed with the saturnine cerate. The latter, he says, will be useful for the relief of the excoriation left after the cessation of the discharge. Small doses of the submuriate of mercury, either alone or in combination with a testaceous powder, will also expedite the cure. If the bowels are very irritable, the hydrargyrus cum creta, or the cinereous oxyde, may be exhibited instead of the calomel. When the health is good, soda, precipitated sulphur, and the testacea will lessen the local inflammation and discharge.

When the irritation is removed, and the crusts are dry and falling off, the unguentum hydrarg. nitrat. much diluted may be used, and the decoction of bark, or the vinum ferri, prescribed.

2. *Porrigo furfurans* begins with an eruption of small *achores:* the excoriation is slight, and the discharge, which is not abundant, soon concretes, and falls off in innumerable thin laminated scabs. At irregular periods, fresh pustules arise, and follow the course of the preceding. The complaint is confined to the scalp, which is affected with itching and soreness; and the hair, which partly falls off, becomes thin, less strong, and sometimes of a lighter colour than natural. This species of porrigo occurs principally in adults, and it is sometimes attended with swelling of the glands in the neck. Dr. Bateman observes, that the treatment requires the hair to be closely cut off the scalp. The branny scabs are then to be gently washed away with some mild soap and water twice a day; and an oil silk cap should be worn. In the beginning, when the surface is moist, tender, and inflamed, the zinc ointment, or one made with ℥ ij. of the cocculus indicus and ℥ j. of lard. Afterward, when the scalp is dry and free from irritation, it may be washed with common soft soap and water; or with a mixture of equal parts of soft soap and unguentum sulphuris. Then the unguentum hydrargyri nitrati, the ung. hydrarg. nitrico-oxydi, the tar and sulphur ointments, or the ung. acidi nitrosi of the *Edinb. Pharm.*, may be employed. These last stimulant applications, however, must be left off if the inflammation and discharge return.

3. *Porrigo lupinosa* is characterized, according to Dr. Bateman, by dry, circular, yellowish-white scabs, set deeply in the skin, with elevated edges, and a central depression, and somewhat resembling, on the whole, the seeds of lupines. These scabs are formed upon separate clusters of *achores*, and attain on the scalp the size of a sixpence; but when on the extremities they are not more than two lines in diameter.

In the treatment of the porrigo lupinosa, the scabs are first to be gently washed off with some soap and water, and the scalp is to be shaved if it be the part affected. When the scabs are difficult of removal, the liquor potassæ, or a weak lotion of muriatic acid, may be used for loosening them. Then the ointment of cocculus indicus is to be applied to the red cuticle, and afterward any of the more stimulant ointments above enumerated.

4. *Porrigo scutulata*, or *ringworm of the scalp*, as Dr. Bateman has observed, makes its appearance in separate patches of an irregular circular shape upon the scalp, forehead, and neck. It commences with clusters of small, light-yellow pustules, which soon break and form thin scabs, which if neglected become thick and hard. If the scabs are removed, however, the surface underneath is left red and shining, but studded with slightly elevated points or pustules. When the disorder is neglected, the patches become confluent, and the whole head affected. Where the disease is situated, the hair becomes lighter in its colour, it falls off, and its roots are destroyed. The porrigo scutulata generally occurs in children three or four years old and upwards, and frequently proves exceedingly obstinate. According to Dr. Bateman, it seems to originate spontaneously in children of feeble and flabby habit, and who are ill fed, uncleanly, and not sufficiently exercised; but he thinks that it is chiefly propagated by contagion, *i. e.* by the actual conveyance of the matter from the diseased to the healthy, as may happen in the frequent contact of the heads of children, the use of the same towels, combs, caps, and hats.

While the patches are inflamed and irritable, it is necessary to limit the local applications to washing the parts with warm water. Even shaving the scalp, which must be repeated at intervals of eight or ten days, produces a temporary irritation. Nothing but a light linen cap is now to be worn, and it must be often changed.

The disease afterward forms dry scabs, and becomes for a time less irritable; but a fresh eruption of achores soon follows, and the inflammation and redness return.

In the inflamed states, Dr. Bateman recommends the use of ointments made either with the cocculus

indicus, submuriate of mercury, oxyde of zinc, superacetate of lead, opium, or tobacco; or else the infusion of poppy-heads or tobacco. When there is an acrimonious discharge, Dr. Bateman prescribes the zinc, or saturnine ointments, the ung. hydrarg. præcip., calomel ointment, or a lotion of lime-water and calomel.

In the less irritable stages, the ung. hydrarg. præcip., the ung. hydrarg. nitrico oxydi, and especially the ung. hydrarg. nitrat., are often effectual remedies. So are the ointments of sulphur, tar, hellebore, and turpentine, and lotions of the sulphates of zinc and copper, or the oxymuriate of mercury. I have often seen a solution of 3 j. of the sulphuret of potassa in a pint of lime-water succeed when most other applications had failed. In the very dry and inert state of the patches, Dr. Bateman has seen the disease removed by a lotion, containing from three to six grains of the nitrate of silver in an ounce of distilled water. The application of the diluted mineral acids, or of a blister, has also been known to put a permanent stoppage to the morbid action.

In general, no local application agrees well if long continued, and it is necessary to have several which must be alternately employed.

The cure may often be expedited by cinchona, chalybeate, and alterative medicines; and attention must be paid to the patient's diet, exercise, &c.

5. *Porrigo decalvans* consist in bald patches, surrounded by hair, which is as thick as usual. It is not known whether any eruption of minute anchores actually precedes the detachment of the hair.

Dr. Bateman remarks, that if the scalp be regularly shaved, and some stimulating liniment be applied to it, this obstinate affection may at length be overcome, and the hair will regain its usual strength and colour. Two drachms of oil of mace in three or four ounces of alcohol are said to make an excellent liniment.

6. *Porrigo favosa* consists of an eruption of the large, soft, straw-coloured, flattened pustules, denominated *favi*, which may occur on any part of the body; but most commonly spread from the scalp, especially behind the ears to the face, or from the lips and chin to the scalp. They are attended with considerable itching, and are most frequently seen in children from six months to four years of age, though adults are also often affected. The pustules pour out a viscid matter, which concretes into greenish or yellowish semi-transparent scabs. When the hair and moist scabs are matted together, pediculi are often generated in great numbers, and aggravate the itching and irritation. If the disease be allowed to increase, the scabs are thickened into irregular masses not unlike honey-comb; and considerable ulcerations sometimes form, especially when the heel and toes or other parts of the lower extremities are affected. The ulcerating blotches are generally soon followed by irritation and swelling of the lymphatic glands, which sometimes slowly suppurate. The contact of the discharge innoculates the disease; thus, in young children, the breast is innoculated by the chin; and the arm and breast of the nurse may be infected in the same way; though adults do not take the complaint so quickly as children.

The porrigo favosa requires the same alteratives internally as the porrigo larvalis. The diet should consist of milk, puddings, and a little plain animal food. When the habit is bad and the glands swelled, bark, chalybeates, and a solution of the muriate of barytes are proper.

As local applications, Dr. Bateman prefers the unguentum zinci, or the ung. hydrarg. præcip. mixed with this or the saturnine ointment, especially when the discharge is copious. He also speaks favourably of the ung. hydrarg. nitrat., the strength of which is to be diminished by an addition of simple cerate, according to the degree of irritation present.

For the preceding particulars I am indebted to Dr. Bateman's valuable Synopsis of Cutaneous Diseases, where the reader, desirous of additional information respecting porrigo, will be amply gratified.

POTASSA ARSENICATA. *Kali Arsenicatum. Arsenias Kali.* ℞. Oxydi albi arsenici, potassæ nitratis sing. ʒ j. Crucibulo amplo igne candenti injice nitrum, et liquefacto adde gradatim arsenicum in frustulis donec vapores nitrosi oriri cessaverint. Solve materiam in aquæ distillatæ ℔iv., et post idoneam evaporationem sepone ut fiant crystalli. These crystals may be given in the dose of one tenth of a grain, thrice a day.—(*Pharm. Sancti Barthol.* 1799.) Justamond strongly recommended the internal exhibition of arsenic in cases of cancer.—(See *Cancer.*)

POTASSÆ CARBONAS. Sometimes given as a palliative in cases of stone: the dose is 3 ij. in ℔j. of distilled water, twice a day.

POTASSA CUM CALCE. This is a strong kind of caustic, chiefly used for making the eschars, when issues are formed in cases of diseased vertebræ, white swellings, morbid hip-joints, &c.—(See *Vertebræ.*) It is also sometimes used, though not so often as it was formerly, for opening buboes and other abscesses. Some are in the habit of making it into a paste with soft soap; they cover the part affected with adhesive plaster, in which there is a hole of the size of the eschar intended to be made; and into this aperture they press the paste till it touches the skin. A bandage is then applied to secure the caustic substance in its situation till the intended effect is produced.

The action of calx cum potassa in this way, however, is more inert and tedious, and perhaps on this account more painful. Hence, many of the best modern surgeons never adopt this method; but, after covering the surrounding parts with sticking plaster, rub the caustic on the situation where it is desired to produce an eschar till the skin turns brown. The end of the caustic must first be a little moistened.

The calx cum potassa is sometimes employed, also, for destroying fungous excrescences.

Before the port wine injection was found to answer best for the radical cure of hydrocele, this caustic was often used as a means of cure.—(See *Hydrocele.*) Mr. Else, a chief advocate for the latter method, used to mix the caustic with powdered opium, by which contrivance, it is said, though not with much appearance of truth, that the sloughs were made with little or no pain to the patient.

Some assert that the potassa alone acts more quickly than when mixed with quicklime. I have not found this to be the fact; and, after trying both, give the preference to the calx cum potassa.

POTASSA FUSA. *Caustic Potassa.* One of the most useful caustics for destroying fungi and making issues; and it was recommended to be used in a particular manner, by Mr. Whately, for the cure of strictures in the urethra. When surgeons prefer opening buboes or any other abscesses with caustic, the caustic potassa is very commonly employed. When surgeons used to cure hydroceles, by destroying a part of the scrotum and tunica vaginalis with caustic, the potassa fusa either alone or mixed with quicklime was made use of.—(See *Vertebræ, Urethra, Strictures of, &c.*)

POTASSÆ SULPHURETUM. *Sulphuret of Potash, Liver of Sulphur.* Two drachms, dissolved in a pint of lime or distilled water, make an excellent lotion for the cure of porrigo. Many other cutaneous affections yield also to the same remedy. When arsenic has been swallowed as a poison, twenty grains of the sulphate of zinc may be given as an emetic of the quickest operation: and after keeping up the vomiting by drinking warm water, and, what is better, sweet oil, some authors recommend making the patient drink as much as possible of a solution of the sulphuret of potash.

PREGNANCY is set down by some writers as preventive of the union of broken bones; but many exceptions to the remark present themselves in practice: I have attended myself a female, six months gone with child, who broke both bones of her leg, yet they grew together again in the usual time.—(See *Fractures.*) Pregnant women also frequently bear operations much better than might be expected. Thus M. Nicod has published a successful amputation of the left leg during pregnancy, in a case where the right tendo achillis was also ruptured. Both the wound and the broken tendon united very well.—(See *Annuaire, Méd. Chir. des Hôpitaux de Paris, p.* 509, *4to. Paris,* 1819.) However, though a severe accidental injury may justify an operation in pregnancy, I consider the removal of a diseased joint, breast, or other important part, quite unjustifiable in this state of the constitution.

PROBANG. A long slender bit of whalebone, with a bit of sponge at its extremity, intended for the examination of the œsophagus, or the removal of obstructions in it.

PROCIDE'NTIA. Prolapsus. A falling down of any part.—(See *Anus, Prolapsus of; Uterus, Prolapsus of, &c.*)

PROSTATE GLAND, DISEASES OF. It is an observation made by Mr. Hunter, that the use of this gland is not sufficiently known to enable us to judge of the bad consequences of its diseased state, abstracted from swelling. His situation (says he) is such, that the bad effects of its being swelled must be evident, as it may be said to make a part of the canal of the urethra, and, therefore, when it is so diseased that its shape and size are altered, it must obstruct the passage of the urine.—(*On the Venereal Disease*, *p.* 169.) A swelling of the prostate gland, however, may be of very different kinds; thus it may depend either upon common inflammation of the part, abscesses, calculi formed within its substance, a varicose enlargement of its vessels, or a scirrhous chronic induration.—(See *Œuvres Chir. de Desault par Bichat*, *t.* 3, *p.* 220.)

Modern anatomists describe the prostate gland as not being itself a very sensible part, and hence it is more subject to chronic than acute disease, to which, however, it is also liable. We have the authority of Desault, Hunter, and Dr. Baillie, for setting it down as the occasional seat of scrofula. The latter physician, after stating that he has seen a common abscess situated in it, adds, that it is also subject to scrofulous disease, as on cutting into it, he has met with the same white curdy matter which is formed in a scrofulous absorbent gland: he has likewise forced out of its duct scrofulous pus.—(*Morbid Anatomy*, *&c.*)

Mr. Lloyd has met with fleshy enlargements of the gland, in the substance of which several small abscesses were formed, containing "a complete scrofulous matter." He has also known enormous enlargements of this gland happen in young men, who were labouring at the same time under other scrofulous disease. Other instances of supposed scrofulous swellings of the same part in young patients are likewise cited by this author, one of which is particularly remarkable, as in it the gland was found after death to be of the size of a child's head, though its natural consistence was not much changed.—(*On Scrofula*, *p.* 107.) Other chronic or, as they are more often called, scirrhous enlargements of the prostate gland, rarely occur in subjects under the age of fifty. To these cases I shall presently return.

Like every other part of the body, the prostate gland is sometimes, but not often, the seat of common phlegmonous inflammation. Mr. Wilson has known two or three instances of this kind take place soon after puberty: one case was from a fall; the other arose without any assignable cause.—(*On the Male Urinary and Genital Organs*, *p.* 327.) There is also a phlegmonous swelling of the prostate gland, sometimes an effect of strictures, as will presently be noticed. As Desault observes, the retention of urine, arising from such a cause, comes on very suddenly, and rapidly increases. The patient at first complains of a sense of heat and weight about the perinæum; and soon afterward of a continual throbbing pain about the neck of the bladder. The pain is severely increased when the patient goes to stool; and there is tenesmus and frequent inclination to make water. However, according to Mr. Wilson, the desire to evacuate the urine is here less constant, than in cases where the inner membrane of the bladder is inflamed.—(*Vol. cit. p.* 327.) The patient feels also as if a large mass of excrement filled the extremity of the rectum, and were ready to come out. If a finger be introduced within the rectum, the swelling of the gland is plainly distinguishable; and, according to J. L. Petit, the projection of the prostate gland in the bowel makes a corresponding hollow groove along the concave side of the excrement, as may be noticed when what is voided is hard. However, Bichat conceives that such an appearance must generally be obliterated as the excrement is passing through the sphincter. When the patient attempts to make water, it is a long while before the first drops come out; and as straining has the effect of propelling the swelled prostate more against the neck of the bladder, it only increases the difficulty, and no urine will come out until such efforts are discontinued. The more violent the inflammation is, the smaller is the stream of urine, and the more acute the pain felt during its expulsion. According to Desault, it is likewise particularly remarkable in such cases, that if an attempt be made to introduce a catheter, the instrument passes without the least resistance as far as the prostate gland, where it stops, and causes great pain. The pulse is hard and frequent; and the patient is exceedingly thirsty and feverish. Desault considered the retention of urine in cases of this kind, and, indeed, in all enlargements of the prostate gland, or other obstructions of the urethra, as generally more dangerous than other retentions, merely depending upon weakness of the bladder, where there is little risk of this organ giving way. When the urethra is free from obstruction, the urine, after distending the bladder in a certain degree, generally oozes through that canal, and the patient may live in this condition for years without any alarming symptoms. But the case is different when the retention of urine depends upon any stoppage or stricture in the urethra. The urine does not then partially escape, but stagnates in the bladder; the distention increases; and if speedy relief be not afforded, a perilous extravasation follows. The danger, however, of such a retention of urine depends very much upon the extent and severity of the inflammation. However, this statement will not apply to the chronic scirrhous enlargement of the prostate, because, as will be presently explained, in this affection some of the urine begins to dribble away after the bladder has become distended in a certain degree.

In cases of phlegmonous inflammation of the prostate gland, antiphlogistic treatment is indicated; especially venesection, leeches to the perinæum and near the anus, the warm bath, emollient clysters, poultices and fomentations, and a low regimen. However, as Desault admits, the efficacy of these means is often too slow, and the symptoms too urgent, to allow the surgeon to wait for the urine to flow of itself. Frequently, also, the distention has so weakened the bladder, that this organ cannot expel its contents; in which event the catheter must be used, though the diminished diameter and altered course of the prostatic portion of the urethra sometimes render its introduction difficult and always very painful. The practical observations respecting the best kind of catheters, and the mode of introducing them in cases of swelled prostate gland, will be more conveniently introduced when the chronic enlargement of this part is considered.—(See also *Catheter*, and *Urine*, *Retention of*.) In every instance of retention of urine from acute inflammation about the neck of the bladder, whether the case be an abscess forming near the anus, or a phlegmonous inflammation of the prostate gland, or other adjacent part, it has always appeared to me, that antiphlogistic and anodyne remedies should first be fairly tried, and the catheter, which always increases the pain and irritation, only used when such means do not afford relief with sufficient expedition.

When a catheter has been introduced ought it to be left in the bladder, or withdrawn, after the discharge of the urine? Its presence, no doubt, will increase the irritation about the neck of the bladder; but, on the other hand, if it be taken out, the surgeon may not be able to introduce it again. No general precept, says Desault, can be laid down on this point. The course which the practitioner will pursue, must depend upon the difficulty he has experienced in getting the instrument into the bladder, and upon the confidence which he may have in his own skill, and which must be founded upon constant success in analogous instances.

According to Desault, when an abscess follows inflammation of the prostate, the body of the gland itself does not suppurate, but only the surrounding parts and the cellular substance which connects its lobes together. This, at least, was what was observed in examining several dead subjects, who were publicly opened in the amphitheatre of the Hôtel-Dieu.

When the symptoms of inflammation have lasted a week, and all this time have continued to increase; when, after this period, they have abated a little, and then become violent again; and when the febrile symptoms grow worse in the evening, and have been preceded by shiverings; there is reason to suspect the formation of matter. It cannot be known whether the pus is collected in one particular place, or diffused. When the matter is external to the gland, the case is less serious than when it occupies the cellular substance connecting the lobes. According to Desault, the latter form of the disease seldom gets well. There are no peculiar symptoms which denote it; the matter does not readily make its way outwards; and the state of things is not clear enough to admit of an incision being made. Besides, Desault doubted whether an incision

could be of much use, since it would probably only discharge the matter in its vicinity.

Things are different when the pus is collected in one place, and is more superficial. If situated between the gland and neck of the bladder, Desault says it will often spontaneously burst into this viscus, or it may be let out with the point of the catheter. It will then either be discharged through the instrument, or come away with the urine. However, according to Mr. Wilson, abscesses of the prostate gland generaly burst into the urethra behind the caput gallinaginis, but sometimes before it; and he has seen more than one instance in which they have burst in the perinæum.—(*On the Male Urinary and Genital Organs*, p. 329.) Should the abscess lie near the rectum and perinæum, and admit of being distinctly felt, Desault conceived that a free opening would expedite the cure. Several cases of this description, I have treated in this way with success: they mostly arose from strictures.

In many cases the use of the catheter is requisite in order to let out the urine, and as the instrument must be left in the passage some time, Desault preferred one made of elastic gum. As Mr. Wilson has remarked, soothing means should also be employed; internal narcotic medicines, anodyne clysters, the mixtura amygdalarum, &c.

Morgagni has taken notice of the retentions of urine arising from the presence of calculi in the prostate gland. The nature of these concretions will be described in the article *Urinary Calculi*. Calculi also sometimes form in or about the prostate gland, when, after lithotomy, the outer part of the wound heals sooner than the bottom. A kind of urinary fistula then ensues; and as the extraneous substance is constantly exposed to the contact of fresh urine, it may increase to a large size. The diagnosis of prostatic calculi is seldom very clear. A retention of urine and an impediment to the emission of the semen are said to be the only symptoms, and these are common to several other affections of the prostate gland and urethra. When the finger is introduced into the rectum, the gland may indeed be felt to be enlarged; but the nature and cause of such enlargement cannot in general be distinguished. In one instance, however, recorded by Dr. Marcet, the calculi could be plainly felt through the coats of the rectum, and a proposal was made to extract them by an incision in that situation; but the patient did not accede to so judicious a measure.—(*Med. and Chem. Hist. of Calculous Disorders*, 8vo. 1817.) When a calculus projects from the prostate gland into the urethra, the end of a sound will strike against it; but then it can rarely be known whether the extraneous substance may not be a calculus that has passed out of the bladder into the urethra, or lies close to the neck of this viscus.

Whether the case be of one description or the other, however, the treatment should be the same; viz. the calculus should be extracted by an incision; and if the situation of the calculi will admit of their being taken out without the bladder itself being cut, this plan should undoubtedly be pursued.

A considerable varicose affection of the vessels of the prostate gland, which is also itself generally somewhat enlarged, is another disease treated of by writers as one cause of a retention of urine. In this case, the water should be drawn off with an elastic gum catheter, which should be kept in the urethra; and a large instrument is to be preferred to a smaller one. For an account of the symptoms of this case, I must refer to *Les Œuvres Chir. de Desault*, t. 3, p. 234. The practice of this author was gradually to dilate the portion of the urethra which passes through the prostate with bougies or elastic catheters, which were worn a long while, and cleaned and changed at proper intervals. I am not aware, that these cases are recognised in the practice of surgery in England.

The most frequent disease of the prostate gland, and of course that which is most interesting to the practical surgeon, is a slow hardening and enlargement of it, sometimes denominated *scirrhus*, whereby its natural size, which is that of a common chestnut, is sometimes gradually changed to that of a man's fist.—(*J. L. Petit.*) According to the observations of Hunter, Desault, and Sir Everard Home, this chronic swelling of the prostate gland is most common in the decline of life; one circumstance in which it differs from scrofulous diseases of the same part, which are well known to happen chiefly in youngish persons. It is observed by Mr. Hunter, that when the prostate gland swells, it does not lessen the surface of the urethra at the part like a stricture; on the contrary, it rather increases it; but *the sides of the canal are compressed together, producing an obstruction to the passage of the urine, which irritates the bladder and brings on all the symptoms in that viscus usually arising from a stricture or stone.* From the situation of the gland, which is principally on the two sides of the canal, and but little if at all on the fore part, as also very little on the posterior side, it can only swell laterally, whereby it presses the two sides of the canal together, and at the same time stretches it from the anterior edge or side to the posterior, so that *the canal*, instead of being round, *is flattened into a narrow groove, and sometimes the gland swells more on one side than the other, which makes an obliquity in the canal passing through it.*

"Besides this effect of the lateral parts swelling, *a small portion of the gland which lies behind the very beginning of the urethra*, swells forwards like a point, as it were, into the bladder, *acting like a valve to the mouth of the urethra*, which can be seen even when the swelling is not considerable, by looking upon the mouth of the urethra from the cavity of the bladder in a dead body. *It sometimes increases so much as to form a tumour, projecting into the bladder some inches.* This projection *turns or bends the urethra forwards, becoming an obstruction to the passage of a catheter, bougie, or any such instrument; and it often raises the sound over a small stone in the bladder, so as to prevent its being felt.*"—(*Hunter, On the Venereal Disease*, p. 169.) The valvular production just behind the beginning of the urethra here described, particularly merits attention, because it is represented by Sir Everard Home as arising from the enlargement of what he considers a newly-discovered part in anatomy, viz. a *third* or *middle lobe* of the prostate gland.—(See *Phil. Trans.* 1806.) In the dissections which Sir Everard mentions as having led to this discovery, "the urinary bladder was distended with water, and the surfaces of the prostate gland, vesiculæ seminales, and vasa deferentia were fairly exposed. This being done, the vasa deferentia and vesiculæ seminales were carefully dissected off from the bladder, without removing any other part. These were turned down upon the body of the prostate gland. An accurate dissection was then made of the circumference of the two posterior portions of the prostate gland, and the space between them was particularly examined. In doing this, *a small* rounded substance was discovered, so much detached that it seemed a distinct gland, and so nearly resembling Cowper's glands in size and shape, as they appeared in the same subject, in which they were unusually large, that it appeared to be a gland of that kind. It could not, however, be satisfactorily separated from the prostate gland, nor could any distinct duct be found leading into the bladder.

"A similar examination was made of this part in five different subjects. The appearance was not exactly the same in any two of them. *In one, there was no apparent glandular substance, but a mass of condensed cellular membrane*; this, however, on being cut into, differed from the surrounding fat. In another there was a lobe, blended laterally with the sides of the prostate gland. These facts (says Sir Everard Home) are mentioned, in proof of its not being always of the same size, or having exactly the same appearance."

This is found also to be the case with Cowper's glands: they are sometimes large and distinct; in other subjects they are scarcely to be detected; and in others again, are in all the intermediate states. The most distinct and natural appearance of this part was in a healthy subject, twenty-five years of age, of which the following is an account. On turning off the vasa deferentia and vesiculæ seminales, exactly in the middle of the sulcus, between the two lateral portions of the prostate gland, there was a rounded prominent body, the base of which adhered to the coats of the bladder. It was imbedded not only between the vasa deferentia and the bladder, but also in some measure between the lateral portions of the prostate gland and the bladder, since they were in part spread over it, so as to prevent its circumference from being seen, and they adhered so closely as to require dissection to remove them; nor could this be done beyond a certain

extent, after which the same substance was continued from one to the other. This proved it to be a lobe of the prostate gland: its middle had a rounded form united to the gland at the base next the bladder, but rendered a separate lobe by two fissures on its opposite surface. Its ducts passed directly through the coats of the bladder on which it lay, and opened immediately behind the verumontanum. By means of this lobe, a circular aperture is formed in the prostate gland, which gives passage to the vasa deferentia. "Previous to this investigation (says Sir Everard), it was not known to me, that any distinct portion of the prostate gland was situated between the vasa deferentia and the bladder."—(*On Diseases of the Prostate Gland, p.* 9, 8*vo. Lond.* 1811.) Notwithstanding this explanation, to the correctness of which most English anatomists have acceded, it is worthy of notice, that Langenbeck, the present distinguished professor of Anatomy and Surgery at Göttingen, in a review of Sir Everard's account, declares, that he has never *in the natural state of the parts*, found the middle lobe, as it is called, which he considers as a partial induration, rising up in the shape of a lobe.—(*Neue Bibl. b.* 1, *p.* 360, 12*mo. Hanover*, 1818.) This dissent would seem extraordinary, if it were not possible to suppose, that it may proceed not from all the subjects at Göttingen differing from Londoners in being destitute of what Sir Everard Home has named the *middle lobe of the prostate gland*, but from Langenbeck's not having traced *in the healthy state of the gland*, any portion which *he thought* deserving of that name. But though differences of opinion may be entertained about the name, none, I presume, can remain about the thing itself, which appears to have been long ago mentioned, though not perfectly described, by Morgagni.—(*Adversaria Anat. 4. animad.* 15.) The paper by Mr. C. Bell, illustrating how far our predecessors had a knowledge of this portion of the gland, seems to me one of his best productions; and it is therefore with pleasure that I refer to it.—(See *An Account of the Muscles of the Ureters, in Med. Chir. Trans. vol.* 3, *p.* 171, *&c.*)—However, as this author impartially acknowledges, it is not because a fact was anciently known, or perhaps only cursorily noticed, that there may not be great merit in reviving the recollection, or perfecting the description of it; and, as far as I can learn, none of the anatomical teachers in this city, previously to Sir Everard's paper, particularly adverted, in the healthy original state of the prostate gland, to the structure which he has pointed out, by whatever name it be distinguished.

According to Sir Everard Home, this lobe, in the earlier periods of life, when the body of the gland is in a sound state, is small; nor does it appear to become enlarged, even when the body and the lateral lobes have been considerably increased in size; but, in subjects of advanced age, this part, as well as the rest of the gland, is usually found somewhat enlarged, even in cases where no disease has been suspected during life.—(*P.* 17.) When the middle lobe begins to enlarge, it presses inwards towards the cavity of the bladder, putting the internal membrane upon the stretch, and communicating to it, by immediate contact, the inflammation which occasioned its own enlargement. Hence, pain in making water, particularly after the last drops are voided, and a desire and straining to discharge more, after the bladder is empty.

As this organ cannot now retain much urine, the desire to make water becomes frequent, and there is commonly more or less constitutional disturbance, or symptomatic fever. In proportion as the middle lobe increases in size, it projects into the cavity of the bladder in the form of a nipple; but after a farther augmentation, it loses the nipple-like appearance, becomes broader, and forms a transverse fold by pushing forwards and stretching the membrane, connecting it to the lateral lobes. "*As the tumour and the transverse fold are situated immediately behind the orifice of the urethra, they are pushed forwards before the urine in every attempt that is made to void it, acting like a valve, and closing up the opening, till the cavity of the bladder is very much distended, when the anterior part of the bladder being pushed forwards, and the tumour being drawn back, in consequence of the membrane of the posterior part of the bladder being put on the stretch, the valve is opened, so that a certain quantity of water is allowed to escape, but the bladder is not completely emptied.*"—*P.* 19.) Sir Everard Home afterward explains, that, as the tumour enlarges, the quantity voided at each time becomes smaller, and that which is retained is increased, until at length the disease becomes so much aggravated, that there is a complete retention of urine. The body of the gland and the lateral lobes, though less disturbed than the middle lobe by the patient's repeated efforts to void the urine, become more or less enlarged; but it is remarked, that they do not preserve either their natural or any regular proportion to the middle lobe, nor do they always swell equally together, the left in some instances becoming much larger than the right.—(*P.* 22.) When he published his first vol. on diseases of the prostate gland, he had seen only the left lobe form the greatest projection within the bladder; but in his second vol., published in 1818, there is an engraving, representing the right lobe thus altered; and he mentions two instances, in which a similar enlargement of the same lobe had taken place. Mr. Wilson has also more than once met with this greater swelling of the right lobe.—(*On the Male Urinary and Genital Organs, p.* 336.) The recollection of these facts will often enable the practitioner to incline the beak of a catheter in the direction by which it may be conducted into the bladder; and thus, as Sir Everard Home has remarked, the surgeon, after trying gently on the left side, and not succeeding, is not to persevere in that direction, but try whether the passage will offer less resistance on the opposite side.

The diseased state of the body of the prostate gland, and of the lateral lobes, here alluded to by Sir Everard Home, he says, is very different from that which is met with in the earlier periods of life, in consequence of strictures of the urethra, and which subsides when the obstruction in that canal is removed. This enlargement of the prostate gland from strictures, he observes, may not be unaptly compared to the swelling of the testicle in gonorrhœa, a case of accidental inflammation in a healthy testicle; while the other disease of the prostate is analogous to the more permanent disease of the latter organ. This author adverts, however, to a few instances, in which the enlargement of the body of the prostate gland from strictures, in persons fifty years of age, did not subside immediately the latter affection was cured, a common bougie stopping at the neck of the bladder, although a catheter, which had a regular curve, readily passed. According to Sir Everard Home, as, in such cases, the patients were able to empty their bladders, it is evident, that there could be no enlargement of the middle lobe. In cases like these, no symptom of importance is produced, and whether the swelling of the prostate readily subsides or not, is of no consequence; though, if the stricture do not return, it will always ultimately diminish.—(*On Diseases of the Prostate Gland, vol.* 1, *p.* 24.) In patients under fifty years of age, Sir Everard Home has rarely found the middle lobe so swelled as to produce retention of urine, or an inability to empty the bladder, notwithstanding the rest of the gland might be much enlarged.—(*P.* 23.) When the middle and one of the lateral lobes project considerably into the bladder together, their surface is sometimes excoriated, and has an ulcerated appearance. Under such circumstances, the pain, after voiding the last drops of urine, is said to be very severe, and attended with spasmodic affections of the neck of the bladder, of the most distressing kind.

According to Sir Everard Home, another effect of a similar enlargement of the prostate gland is, to render its secretion extremely viscid and very abundant. A question might arise about the real source of this ropy mucus, and some might infer that it was secreted by the bladder; but that it comes entirely from the inflamed prostate gland is proved, says this gentleman, by its having been found in one instance with one extremity floating in the bladder in the dead body, while the other extremity appeared divided into small filaments, terminating in the orifices of the excretory ducts of the gland at the verumontanum. The quantity of secretion is observed to depend more upon the degree of irritation, than the actual enlargement of the gland, and, as this increased secretion happens in cases of swelling of this part from strictures, where the body and lateral lobes are alone affected, it is inferred, that the disease of the middle lobe only contributes to this effect by keeping up a straining and disturbance of every part of the gland.—(*P.* 32.) The internal membrane

of the bladder inflames, and becomes extremely irritable, so that, even when the quantity of urine is small, there is a great deal of straining. When the size and form of the tumour are such as to allow the greater part of the urine to pass, though with great effort, Sir Everard states, that the symptoms may continue nearly the same for months; liable, however, to occasional aggravations from slight causes, and becoming more or less relieved, when these are removed. Nay, he observes, that the symptoms may even lessen, although the disease is not at all diminished; a circumstance which is ascribed to the muscular coats of the bladder having acquired greater strength, and the internal membrane having lost, from habit, the sensibility which it possessed in the earlier stage.—(*P.* 34.) He farther explains, that, in this disease, when the inside of the bladder is inflamed, filamentous portions of coagulating lymph are thrown off from it, which, when the inflammation increases, subside in the urine evacuated, looking not unlike white hair-powder; and when the irritation is very violent, perfectly formed pus is met with in the urine.—(*P.* 35.) After the inflammation subsides, the bladder becomes again capable of retaining a larger quantity of urine, though its power of completely emptying itself is still farther diminished.

According to Mr. Wilson, the symptoms which generally attend an enlarged prostate gland, are similar to those of an irritable bladder:—constant, heavy, dull pain in the gland, and sometimes sharp lancinating pains, darting from it to the urethra, and occasionally to the bladder and ureters. Frequent calls to void the urine, which is passed with difficulty, only a small quantity being discharged at a time, as more or less always remains behind in the bladder. A complete retention of urine may be produced, so that not one drop will pass, although much straining is used. Great difficulty in expelling the feces; and after each evacuation, a feeling is still experienced, as if the gut were not yet emptied. During the efforts to expel the urine and feces, a quantity of the mucous secretion of the prostate gland is not unfrequently forced out. Most of these symptoms, as Mr. Wilson observes, are similar to those produced by stone, and, therefore, when they occur, the gland should be examined by the rectum, and if it be not found diseased, a sound should be introduced into the bladder.—(*On the Male Urinary and Genital Organs, p.* 339.) The particular differences between the symptoms of stone, and those arising from disease of the prostate gland, are explained in the article *Lithotomy.*

Mr. Hunter first pointed out a fact, which the practical surgeon should never forget, viz. that the swelling of what is now called the middle lobe of the prostate gland, often raises the sound over a small stone in the bladder, and prevents it from being felt.—(*On the Venereal Disease, p.* 170.) Hunter also first noticed another circumstance well deserving recollection, viz. that an enlargement of the same part may account for the disappearance of all the symptoms of stone in patients who have already suffered greatly from them, as the swelling prevents the calculi from falling down upon and irritating the neck of the bladder. These truths are exemplified by cases, which are highly interesting. It appears also probable, from the observations of Sir Everard Home, that an enlargement of the middle lobe conduces to the formation and lodgement of calculi in the bladder, partly by preventing the evacuation of small ones through the urethra, and partly by hindering the bladder from completely discharging its contents.—(*Vol.* 1, *p.* 40.) Lastly, it is explained, that in disease of the prostate gland, patients secrete less urine than natural, and that death is sometimes produced by the retention of urine suppressing the secretion altogether. In cases of enlargement of the middle lobe, one symptom on which Sir Everard Home lays great stress is, hemorrhage produced by riding on horseback.—(*Vol.* 2, *p.* 27.) Inflammation and even ulceration of the membrane covering the middle lobe, he says, are more frequent than he was at first aware of, and are produced by the rough introduction of instruments. Hence, the burning heat at the neck of the bladder, the great pain and distress attending the passage and the continuance of an instrument, the occasional necessity of taking it out, and the duration of the pain for some time afterward.—(*Vol. cit. p.* 29.)

According to Mr. Wilson, in a case of what is named scirrhous prostate gland, the enlargement at first takes place slowly, attended with pain, and no particular alteration of the structure is apparent in the gland when examined in this stage after death, nor is any change discoverable, when the part is felt from the rectum in the living patient. As the disease proceeds, the structure of the whole gland changes, and the part enlarges sometimes regularly, so as to preserve its shape, to the size of a moderate orange; sometimes very irregularly, projecting in a lobulated manner. When the gland in this state is cut into, its substance feels firm, the cut surface is of a whitish-brown colour, and the membranous septa extending through it in various directions are often very strongly marked. In general, before the urethra and bladder are opened, the gland appears most enlarged laterally. It also swells backwards towards the rectum, producing that appearance of the excrement particularly noticed by J. L. Petit, and already mentioned in speaking of common inflammation of the gland. Mr. Wilson farther states, that its anterior part is generally least enlarged, because its connexion with the pubes prevents it from passing far forwards. However, this gentleman has seen some instances, in which the enlargement above or in front of the urethra was considerable. The extent of the lateral and posterior swelling may be readily felt with the finger, introduced within the rectum. That these very irregular windings in the prostatic portion of the urethra are frequently occasioned by the disease, is also confirmed by Mr. Wilson's experience, and numerous preparations in the museum of the College of Surgeons. "In the progress of the enlargement, the two sides do not always swell equally; one often enlarges most, and often swells more in one particular part than another. This produces a lateral bend, or obliquity in the passage, which will of course increase the difficulty of passing the urine, and of introducing the catheter. I have seen, from the irregularity of the lateral swelling, the passage through the gland bend in succession to both sides."—(*On the Male Urinary and Genital Organs, p.* 332.)

As every considerable enlargement of the prostate gland is attended with great difficulty of voiding the urine, the muscular coat of the bladder always becomes more or less thickened, in consequence of the efforts which it is obliged to make.

In relation to the third or middle lobe, it is to be observed, that, from some dissections made by Mr. Shaw, it would appear, that in many cases the enlarged portion of the prostate projecting into the bladder, is not the third lobe, but a part of the gland situated more forwards.—(See *Bell's Surgical Obs. vol.* 1, *p.* 223, *&c.*)

According to Sir Everard Home, a stricture may be distinguished from an enlargement of the prostate gland by the following circumstances: the distance of the obstruction from the external orifice is to be determined by passing a soft bougie, which is to be left in the canal for a minute, so as to receive an impression from the obstruction. If the bougie does not pass farther than seven inches, and the end is marked by an orifice of a circular form (it is immaterial as to the size of the orifice), the disease is certainly a stricture; but if it passes farther on, and the end is blunted, a disease in the prostate gland is to be suspected. This in general may be ascertained by the possibility of passing into the bladder a flexible gum catheter with a stilet, very much curved, which in most cases of enlargement of the gland may be accomplished.

On the subject of the causes of a scirrhous enlargement of the prostate gland, it appears to me, that little certain is known, excepting that it is a disease seldom met with under the age of fifty. Desault suspected that it was sometimes venereal, and common in individuals, who had repeatedly had gonorrhœa.—(*Traité des Mal. Chir. t.* 3, *p.* 238.) I believe neither of these sentiments is entertained by the best surgeons of the present day. According to Sir Everard Home, it is a rare occurrence for a man to arrive at eighty years of age, without suffering more or less under disease of this part. "The more common causes (says he) of inflammation of the prostate gland are, full living of every kind, inebriety, indulgence to excess with women, a confined state of the bowels, and exposure to the effects of cold; indeed, whatever increases the circulation of the blood in these parts (the genitals, I suppose) beyond the healthy standard, may become a cause of inflammation in this gland, the blood-vessels of which lose their

tone in the latter periods of life."—(*On Diseases of the Prostate Gland, vol.* 1, *p.* 18, 19.) If we are to credit another statement, the disease occurs most frequently either in persons who have not used the genital organs so much as nature intended, or in others who have led a life of excess.—(*Wilson on the Urinary and Genital Organs, p.* 332.) It seems to me better to confess that the etiology of this complaint is unknown. Nor are we rendered much wiser by conjectures about the effects of horse exercise, or those of a retarded venous circulation in old subjects, in creating a tendency to the disease. I have known several persons afflicted, who had led very sedentary lives.

I am afraid that the observation formerly made by Mr. Hunter still continues true, which is, that a certain cure for the scirrhous enlargement of the prostate gland is not yet discovered. But though such is the fact, surgery is undoubtedly capable of affording a great deal of relief, so as to lengthen the patient's days, and render them much more comfortable. This is accomplished principally by anodyne medicines, and drawing off the patient's water, when he cannot void it himself, either at all, or but imperfectly, and with considerable straining and suffering. As a temporary relief from pain, and also as a means of removing spasm, opiate clysters should be administered once or twice a day.—(*Hunter, p.* 174.) Scrofulous enlargements of the prostate gland, occurring in younger subjects, are probably more under the control of judicious treatment. Thus, Mr. Hunter informs us that in several cases he had seen hemlock of service. "It was given upon a supposition of a scrofulous habit. On the same principle (he adds), I have recommended sea-bathing; and have seen considerable advantages from it, and in two cases, a cure of some standing." In one case, burnt sponge had reduced the swelling; and in another, the same effect was produced, and the irritability of the bladder lessened, by means of a seton in the perinæum. After the healing of the seton, however, the symptoms returned, and on a trial of the plan again, the former good effects were not experienced from it. Some years ago, I attended a gentleman under Mr. Lawrence, who was trying the effect of an issue in the same situation. In these cases, the pilulæ hydrargyri cum conio (see *Pilulæ*) have been very commonly prescribed, as an eligible alterative. Sir Everard Home mentions an instance in which suppositories of opium and hemlock, passed up the fundament and allowed to dissolve there, gave more relief than any other plan; not only lessening the irritation, but producing a diminution of the projection of the gland.

In the first stage of the enlargement of the middle lobe, when there is no absolute obstruction to the passage of the urine, Sir Everard recommends bleeding from the loins, opiate clysters, and the pulv. ipecac. comp.—(*On Diseases of the Prostate Gland, vol.* 1, *p.* 70.) The tepid bath, the use of which he formerly advised, he now condemns, as a practice "as little applicable to this disease, as putting the head in warm water would be to remove the symptoms of apoplexy: if any applications are to be made to the parts, they should be such as produce cold."—(*Vol.* 2, *p.* 83.) In this stage, he observes that catheters and bougies should on no account be introduced, more especially those of the metallic kind, since they produce a degree of disturbance, which the parts are not in a state to bear, and if unskilfully employed, they will increase the swelling and bring on a complete retention of urine. Sir Everard is an advocate for keeping the bowels open, for which purpose he prefers the infusion and tincture of senna, with the tartrate of potash.—(*Vol.* 2, *p.* 84.) If, in defiance of these means, the patient becomes unable to make any water, or although able to pass a few ounces, is every hour obliged to make the attempt, and, after much straining, discharges only the same quantity, Sir Everard directs a flexible gum catheter, without a stilet, to be passed into the bladder, in the gentlest manner possible. This instrument is to be kept introduced with the catheter bracelet, or retainer, made and sold by Mr. Weiss, of the Strand, and the water drawn off at regular intervals, not only till the first symptoms go off, but till the bladder can retain the urine for the usual length of time, and what is voided has the appearance of healthy urine. If, when the catheter is withdrawn, the patient should not be able to empty his bladder, it must be reintroduced, and after six or seven days taken out again. When the disease is somewhat more advanced and the patient cannot keep himself quiet, the above practice of course cannot be adopted, and it becomes necessary to pass the catheter three or four times a day. But even in such a case, when irritation is brought on by accidental circumstances, Sir Everard recommends keeping the instrument in the bladder until the attack has subsided.—(*Vol.* 2, *p.* 92, 96.) This gentleman finds, that for cases of diseased prostate, the common flexible gum catheters, originally made straight, are disadvantageous, as it is a long while before they can be made to keep a permanent curved form. "When (says he) the curvature of the catheter is no part of its original formation, although it may have been produced by being long kept in a curved state, yet, when allowed to remain in the bladder, it gradually returns to its straight form by being moistened, and when it has acquired it, the point is no longer kept directed upwards in the cavity of the bladder, but is constantly pressing against the posterior coats, pushing itself out of the urethra, and the irritation it gives the muscular coat of the bladder will often be the means of its being expelled by a spasm with considerable violence."—(*On Diseases of the Prostate Gland, vol.* 2, *chap.* 5.) Sir Everard farther informs us, that Mr. Weiss, No. 33, in the Strand, has at length succeeded in making flexible gum catheters, originally curved, so that they always retain their shape. Their polish is great, and they can be had of any size: they are also made particularly strong, as a quality necessary to secure them from being broken in violent attacks of spasm. Sir Everard states, that he has kept them fifteen days in the bladder, without their being spoiled by the urine or mucus; whereas, common French and English catheters become in a shorter period so rough as to be unfit for farther use. Metal catheters, he asserts, should never be employed but in cases of necessity, where the patient cannot be relieved by milder means.—(*Vol.* 2, *p.* 87.) To such instruments he ascribes the frequently-noticed ulceration of the middle lobe, the abrasion of its surface, the wounds through its substance, the general inflammation of the whole internal membrane of the bladder, and quick destruction of the patient's life. The gum catheter, however, is to be as large as the urethra will easily admit, in order that it may more readily disengage itself at the turns into the bladder.—(*Vol.* 1, *p.* 75.)

According to Desault, a large catheter generally answers better than a small one, and it may either be of silver or elastic gum. The latter, though the best for the purpose of being kept in the passage, he says, has not always sufficient firmness to get through the obstruction in the canal, not even with the aid of a stilet. In this respect, a silver catheter is sometimes preferable. But whatever may be the kind of catheter employed, it generally passes as far as the prostate with perfect facility, where it is stopped, not only by the narrowness, but also by the new curvature of the passage.

For the prostate cannot be enlarged, without pushing forwards and upwards, or to one side, that portion of the urethra behind which it is situated. This circumstance ought never to be forgotten in regulating the length and direction of the beak of the catheter, which should also be longer, have a more considerable curvature, and be more elevated at the time of its introduction, than in other cases of obstruction in the urethra.

In swellings of the prostate gland, Mr. Hey has particularly pointed out one advantage, which belongs to elastic catheters, viz. that their curvature may be increased while they are in the urethra. This gentleman was introducing an elastic gum catheter in a patient, whose prostate gland was much enlarged, and finding some obstruction near the neck of the bladder, he withdrew the stilet, in doing which, he accidentally repressed the tube, which then went into the bladder. In fact, he found that the act of withdrawing the stilet increases the curvature, and lifts up the point of the catheter —(*Pract. Obs. in Surgery, p.* 399, *edit.* 2.) For farther remarks connected with this subject, see the articles *Catheter*, and *Urine, Retention of.* Sir Everard Home states with confidence, that if the symptoms of the foregoing disease be prevented in their early stage from increasing by the treatment which he has recommended, the disease will get well.—(See *J. Hunter's Treatise on the Venereal Disease, p.* 169, *&c. 2d ed. 4to. Lond.* 1788. *Baillie's Morbid Anatomy. P. J. Desault, (Œuvres Chir. t.* 3, *p.* 220, *&c. 8vo. PSEUDOSYPHILIS. (From ψευδὴς, false, and *syphilis*, the venereal disease.) Disease resembling the venereal, but not really of this nature.—(See *Venereal Disease.*)

PSOAS ABSCESS. See *Lumbar Abscess.*

PSORIASIS. *Scaly Tetter.* A disease of the order squamæ, in Dr. Bateman's Synopsis. It is attended with more or less roughness and scaliness of the cuticle, and a subjacent redness. The skin is often divided by deep fissures; and the complaint is generally attended with constitutional disorder, and liable to cease and return at certain seasons. For a particular account of its varieties and treatment, see the above work.

PSOROPHTHALMY. (From ψώρα, the itch, and ὀφθαλμία, an inflammation of the eye.) An inflammation of the eyelids, attended with ulcerations which itch very much. Beer actually understands by the expression, such a disease, from the sudden repression of the itch, or the infection of those parts with psoric matter.—(*Lehre von den Augenkr. b.* 1, *p.* 566.) Weller not only adopts the same notion, but makes an addition to it, by extending the term also to cases in which the eyelids are affected with psoriasis, porrigo, and impetigines.—(*Manual of the Diseases of the Eye, vol.* 2, *p.* 264.) By psorophthalmy, the late Mr. Ware meant a case in which the inflammation of the eyelids is attended with an ulceration of their edges, upon which a glutinous matter lodges, incrusts, and becomes hard, so that in sleep, when they have been long in contact they become so adherent that they cannot be separated without pain. He has remarked, that "the ulceration in the psorophthalmy is usually confined to the edges of the eyelids; but sometimes it is seen to extend over their whole external surface, and even to excoriate the greater part of the cheek. In cases of the latter kind, the inflammation which accompanies them has often much the appearance of an erysipelas, and will receive most relief from cooling applications. The use of the citrine ointment, which will hereafter be recommended, must in such instances be deferred until the irritability of the skin is in a good degree abated.

"This disorder is also sometimes attended with a contraction of the skin of the lower eyelid; in consequence of which, that lid is drawn down and the inner part turned outwards, so as to form a red, fleshy, and most disagreeable appearance, called ectropium. Whenever this happens, it proves the complaint to be of the most obstinate nature; though it is generally removed by the cure of the psorophthalmy, which is the occasion of it."—(*Remarks on Ophthalmy, &c. p.* 112.) Mr. Ware recommended for the cure of this disease the unguentum hydrargyri nitrati melted and rubbed with the end of the fore-finger, or the point of a small pencil brush, into the edges of the affected eyelids every night at bedtime. A plaster of ceratum album was then put over the eyelids to keep them from adhering together. If they still adhered in the morning, they were cleaned with milk and butter well mixed together. In a few cases it is necessary to touch the ulcers formed on the edge of the eyelid, after the small-pox, with the argentum nitratum. When the globe of the eye is inflamed, the vinous tincture of opium is applied, as directed in the article *Ophthalmy.* In scrofulous subjects, alterative medicines, an issue or perpetual blister, and attention to diet, &c., are necessary.—(See *Ware on Ophthalmy, &c.*)

In the treatment of psorophthalmy, Beer lays considerable stress upon the necessity of cleanliness. The itchy places he directs to be frequently washed with a tepid infusion of scordium, and afterward well dried. When the uneasiness and tension of the skin are thus quite removed, Beer adds to the preceding infusion some of the sulphuret of potash, the proportion being at first small, and gradually increased. This plan is to be followed until the ulcerations dry, and the scabs fall off of themselves, leaving the subjacent skin yet red and sensible, and sometimes moist; in this state, a small bit of the annexed salve may be smeared with a camel-hair pencil along the edges of the eyelids, and upon the affected points of the skin: ℞. Butyri recentis insulsi, ʒ ss. Cupri sulphatis, gr. x. Camphoræ, gr. iv. Tutiæ ptt. gr. vj. Misce. If the disease prove obstinate, Beer recommends Hufeland's salve, which consists of equal parts of fresh butter, yellow wax, and the pulv. hydrarg. nitrico-oxydi rubr.; and, in still more inveterate cases, Janin's eye-salve, which he says must rarely be used oftener than every other day. In the psorophthalmy, conjectured by Beer to depend upon the sudden cure of the itch, he states, that internal medicines are necessary, as antimonials joined with sulphur and camphor. He also praises sulphur baths, and irritating the part of the skin where the itch has receded, by the application of antimonial ointment; or, if such part should be very far from the eyes, he advises such ointment to be rubbed on the skin behind the ears. Attention to diet is particularly enjoined, and eating pork, lard, and substances difficult of digestion is prohibited.—(*B.* 1, *p.* 569, *&c.*)

PTERYGIUM. (Dim. of πτέρυξ, a wing.) As Scarpa remarks, surgeons usually apply the term "*pterygium*" to that preternatural, reddish, ash-coloured, triangular little membrane which most frequently grows from the internal angle of the eye, near the caruncula lachrymalis, and gradually extends over the cornea, so as to cause considerable impediment to vision.

The disease, however, presents itself sometimes in the form of a semitransparent thin grayish membrane, not furnished with many visible vessels; and sometimes as a thick, red, fibrous mass, very like muscle, being very prominent even on the cornea, where it seems to terminate in a substance like tendon, and it is observed to be pervaded by numerous blood-vessels. The first is the *pterygium tenue* of Beer; the second, the *pterygium crassum* (*Lehre von den Augenkr. b.* 2, *p.* 636), or the membranous and fleshy pterygia of other writers.

Though the pterygium most commonly proceeds from the internal angle (also *Beer, b.* 2, *p.* 637), sometimes it arises from the external one, and in rare instances from the superior or inferior hemisphere of the eyeball. But whatever be its origin, its figure is invariably that of a triangle, with its base on the white of the eye, and its apex more or less advanced over the cornea, towards its centre, and that of the pupil. Indeed, there are a few cases in which two or three pterygia of different sizes occur on the same eye, and are arranged round its circumference at interspaces of various breadths. Their points are directed towards the centre of the cornea, where, if they unfortunately conjoin, the whole of that transparent membrane becomes covered with an opaque veil, and a total loss of sight is the consequence. The occurrence of more than one pterygium on the same eye is very rare: Beer, in all his practice, met with but two cases of double pterygium, and with only one of three pterygia on the eye.—(*B.* 2, *p.* 638.)

According to Scarpa (whose observations apply chiefly to the membranous form of the disease), chronic varicose ophthalmy, with relaxation and thickening of the conjunctiva, opacity of the cornea, and the pterygium, only differ in the degree of the disease. In reality, all the three complaints consist of a more or less extensive varicose state of the vessels of the conjunctiva, combined with a degree of preternatural relaxation and thickening of that membrane.

In chronic varicose ophthalmy, the extraordinary amplitude and knottiness of the vessels, the flaccidity and thickening of the conjunctiva, are limited to the white of the eye. In opacity of the cornea certain veins even dilate, and become knotty for some way over that delicate layer of the conjunctiva which is continued over the surface of the cornea. In the pterygium an extraordinary swelling of this subtile membranous expansion is added to the varicose state of its veins. Hence the pterygium seems at first like a new membrane formed on the cornea, while it is really nothing more than the delicate continuation of the conjunctiva just mentioned, deprived of its transparency, and degenerated in consequence of chronic ophthalmy into a thick opaque membrane, on which there is a plexus of varicose blood-vessels. Consequently, in the case of pterygium, there is no new production, but only an alteration of one of the thin transparent membranes which naturally cover the eye. The following circum

stance illustrates, says Scarpa, the veracity of the preceding statement. The incipient pterygium may be cured in the same manner as opacity of the cornea, viz. by merely cutting off that portion of it which is situated at the junction of the cornea with the sclerotica, without detaching the whole of it from the surface of the former membrane; just as is practised in the opacity of the cornea, in order to destroy the communication of the varicose veins of the conjunctiva with their trunks, the ramifications of which produce and maintain the disease.

That the pterygium is only the natural, delicate, transparent expansion of the conjunctiva on the cornea, converted for a certain extent into a pulpy flaccid varicose membrane, may be inferred (continues Scarpa) from the folds which the pterygium and conjunctiva form at the same time, when the morbid eye is turned towards the origin of the disease. The same inference is equally deducible from the tension occasioned in both these parts whenever the eye is moved in the opposite direction. We become still more convinced of the fact on observing, that in the first position of the eye, both the pterygium and the corresponding portion of the conjunctiva (which is equally relaxed, varicose, and reddish, may be easily taken hold of with a small pair of forceps and raised together in the form of a fold.

Mr. Guthrie does not agree with Scarpa, that chronic varicose ophthalmy with relaxation and thickening of the conjunctiva, nebula of the cornea, and pterygium are diseases differing only in degree. On the contrary, he asserts that a true pterygium is very rarely the consequence of chronic inflammation. The nebula, he observes, is never of the spear-formed shape of the pterygium, but always irregular, its progress rather from than towards the cornea, and the width of its base not equal to that of the latter disease.—(See *Operative Surgery of the Eye*, *p.* 128.)

The pterygium is observed by Mr. Travers to be most prevalent in warm climates.—(*Synopsis, &c. p.* 101.) It is also said to be most frequent in old people, though Mr. Wardrop and Dr. Monteath have seen it in very young infants.—(*Weller's Manual of the Diseases of the Eye, vol.* 1, *p.* 218.)

The constancy of the triangular figure of the pterygium, with its basis on the white of the eye, and its apex on the cornea, is one of its principal diagnostic characters, by which the true disease may be discriminated from every other soft, fungous, reddish excrescence obscuring the cornea.

Another distinguishing character of pterygium, as Scarpa has observed, is the facility with which the whole of it may be taken hold of with a pair of forceps, and raised into a fold on the cornea. Every other kind of excrescence attached to this membrane continues firmly adherent to it, and cannot be folded and raised from the surface of the cornea in any manner whatever. This particularity is of the highest importance in the treatment; for the genuine pterygium may be cured by simple means, while fungous excrescences of the cornea can only be radically removed and perfectly cicatrized with the utmost difficulty.

Scarpa's belief in the reality of a *malignant* or *cancerous* pterygium must appear a doctrine requiring confirmation, when it is considered that Mr. Travers makes no mention of the disease assuming this character, and Beer distinctly states, that in a practice of thirty-two years, he has cured 376 pterygia of various sizes and thickness, without one bad symptom or consequence. And hence he justly concludes, that the disease is strictly local.—(*B.* 2, *p.* 641.)

The true benign pterygium, says Scarpa, which has a triangular figure, is ash-coloured or pale-red, is free from pain, and admits of being raised in the form of a fold on the surface of the cornea, may be cured by cutting the opaque triangular little membrane accurately from the surface of the cornea, which is in part covered by it. But as the pterygium is nothing but a portion of the delicate transparent layer of the conjunctiva, converted into a thick, opaque tunic, it follows that the pterygium cannot be removed in any way without the spot which it occupies on the cornea being bereft of its natural external covering, and this part of the membrane rendered more or less opaque.

Scarpa's experience enables him to state, however, that the superficial indelible speck remaining on the cornea after the removal of the pterygium is always less extensive than the space previously occupied by the disease.

It is customary (says Scarpa) to remove the pterygium by making the incision on the cornea, and extending it over the white of the eye as far as the base of the disease reaches on the conjunctiva; so that when the pterygium grows from the internal angle of the eye, most surgeons continue the section as far as the caruncula. This practice is disadvantageous, first, because it denudes too much of the white of the eye; secondly, because, in consequence of the large portion of the conjunctiva removed at the base of the pterygium, and in consequence of the direction of the wound, the cicatrix in the white of the eye forms an elevated frænum, which, like a little cord, keeps the eyeball approximated to the caruncula lachrymalis, and destroys the freedom of its motions, particularly towards the external angle.

In the treatment of pterygia with bases extending far in the white of the eye, Scarpa prefers detaching them at their apex, as far as the junction of the cornea with the sclerotica, and then to separate them at their base by a semicircular incision, comprehending one line in breadth of the substance of the conjunctiva, and made in a direction concentrical with the edge of the cornea. Scarpa has observed, that in this mode of operating, the subsequent cure takes place sooner than when the common method is adopted; the cicatrix occasions no sort of frænum, and the conjunctiva, circularly stretched by the cicatrix, lies smoothly over the white of the eye, and loses that relaxation and varicose state which he considers as the groundwork of the pterygium. Such attention, however, is not requisite when the pterygium is small, and its base does not extend far in the white of the eye.

The operator, after desiring the patient to move his eyeball towards the part corresponding to the base of the pterygium, is to take hold of the membrane with a pair of forceps held in his left hand, and pinch it into a fold, at about one line from its apex. The duplicature is now to be raised and drawn out gently, until a sensation of something giving way is felt, which indicates the detachment of the pterygium from the delicate cellular texture, by which it is connected with the subjacent cornea. Next, by means of a pair of scissors, the surgeon must dissect this fold as closely as possible from the cornea, proceeding from the apex towards the base of the pterygium. The section being completed to where the cornea and sclerotica meet, the fold is to be again elevated still more, and with one stroke of the scissors the pterygium and the relaxed portion of the conjunctiva forming its base are to be detached, as concentrically and closely to the cornea as possible. This second incision will have a semilunar shape, the horns of which ought to extend two lines beyond the relaxed part of the conjunctiva in following the curvature of the eyeball.

When the operation is finished, the surgeon must promote the hemorrhage by washing the part with warm water, and then cover the eye with dry lint, or lint moistened in the liquor plumbi acet. dilutus, kept on with a bandage that does not make too much pressure.

If no particular symptoms arise, such as pain, tension of the eye, considerable tumefaction of the eyelids, it is sufficient to wash the eye and inside of the eyelids three or four times a day with a warm lotion of mallows, and carefully keep these parts from being exposed to the air without compressing them. If the symptoms just mentioned should occur, antiphlogistic treatment must be adopted.

On the fifth or sixth day, at latest, after the operation, all the surface from which the pterygium was cut appears yellowish, and covered with a fluid like mucus. The edges of the wound, and the adjoining part of the conjunctiva, assume a reddish colour. Afterward, the surface of the wound contracts more and more daily, and at length completely closes.

All local stimulants are to be avoided, and it is not till the wound is healed that the zinc collyrium, containing a few drops of camphorated spirit of wine, should be used three or four times a day, for the purpose of obviating the relaxation of the conjunctiva and its vessels.

In the early stage of pterygium, while the membrane is as thin as a cobweb, Scarpa considers it unnecessary to deprive the cornea of its natural covering; and that it is quite enough to cut off a portion of it in

order to intercept all communication between the dilated venous ramifications of the pterygium and the varicose trunks in the white of the eye. This is accomplished by cutting out, with a pair of forceps and scissors, a semilunar piece of the conjunctiva, at the point where the cornea and sclerotica conjoin, and exactly at the base of the incipient pterygium, just as is practised for opacity of the cornea. The recent pterygium is observed to disappear gradually after the operation, or to change into a slight dimness of the cornea, extending over a part of the space previously occupied by the disease. This opacity is commonly much more trivial than what follows a cicatrix. Acrel, in his *Surgical Observations*, mentions having successfully treated an incipient pterygium in this manner. Scarpa has also tried the plan several times with success. Such treatment must be better than merely making two or three deep cuts or scarifications, in the membrane, near the edge of the cornea, as advised by Beer. —(*B.* 2, *p.* 641.) And in proof of the uncertainty of the latter method, we find Beer himself speaking of the necessity of using stimulating applications, like powdered sugar, alum, the vinous tincture of opium, &c. if the operation is not of itself sufficient. In the *pterygium crassum*, Beer recommends the knife as the best means of cure; but he differs essentially from Scarpa, not merely in preferring a knife to the scissors, but in beginning the operation by making a deep cut through the base of the pterygium in the white of the eye, from which point he continues the dissection of the pterygium till this is all removed as far as its apex on the cornea, when he either uses the knife or scissors, as most convenient.—(*B.* 1, *p.* 643.)

Mr. Guthrie, who acknowledges the correctness of Scarpa's objections to removing a large pterygium to a great extent towards the caruncula lachrymalis, adopts a middle course between the methods of Beer and Scarpa, and removes half of the pterygium from the apex towards the base.—(*Vol. cit. p.* 130.)

Beer mentions, that it sometimes happens, especially in cases of thin pterygia, that the disease stops at the edge of the cornea, and spreads no farther as long as the patient lives.—(*B.* 2, *p.* 641.) Under such circumstances, of course, the complaint will give no trouble, and may be left to itself, as particularly advised by Mr. Travers.—(*Synopsis, &c. p.* 274.) When, however, it encroaches upon the sight, this gentleman says that "it should be raised by dissection as close as possible to the margin of the cornea, and the relaxed portion of the membrane removed by an incision *midway between the base of the pterygium and the cornea*, and concentric to that membrane." For farther information, consult *J. Wardrop, Essays on the Morbid Anatomy of the Human Eye, vol.* 1, *p.* 22, *&c.* 8*vo. PTOSIS. (From πίπτω, to fall down.) *Blepharoptosis.* An inability of raising the upper eyelid. According to Beer, ptosis always arises from a considerable relaxation and extension of the common integuments of the upper eyelid, which hang down in a kind of fold over the fissure of the closed palpebræ, and when the levator muscle has been more or less weakened by the same causes which have produced this state of the skin, the weight of the redundant integuments prevents the eyelid from being properly opened. Hence, when the patient tries to raise the eyelid, the efforts of the levator muscle may be seen; but the object cannot be perfectly accomplished. With the exception of the inability of raising the upper eyelid, the patient has not the slightest ailment; the eye is not at all red, though, when opened, it does not bear the light well, on account of not being accustomed to the stimulus; no stillicidium lachrymarum is observable; and the edge of the eyelid, with all the eyelashes quite dry, is seen directly the part is elevated with the thumb. When the relaxed fold of the skin is taken hold of between the thumb and fore-finger, without pulling or stretching it, but only just so as to take off the weight opposed to the levator muscle by the redundance of skin, the patient is immediately able to raise the eyelid without any difficulty; but as soon as the surgeon relinquishes his hold of the skin, the part falls down again. The relaxed fold of skin is sometimes situated rather over the outer commissure than the middle of the eyelid, in which case, the latter part can be opened towards the nasal commissure, and the eyeball becomes habitually rotated towards the nose for the purpose of vision, whereby strabismus and, if the disorder be not soon rectified, an obliquity of sight are occasioned.

A prolapsus of the upper eyelid, Beer observes, may be the consequence of any inflammation of the part, accompanied with considerable œdema or ecchymosis as happens from severe wounds of the forehead, eyebrow, or the eyelid itself, particularly when no attempt is made to unite the parts by the first intention. The infirmity may also be the consequence of ophthalmy, that has been either long neglected or badly treated with relaxing poultices; and it is said, that scrofulous patients have a disposition to the complaint.—(*Beer, b.* 2, *p.* 109—111.)

The case, as described by this author, may be cured by the excision of a long slip of skin from the eyelid, just broad enough for the removal of the redundant quantity. For taking hold of the portion of integuments, Beer employs forceps, the extremities of which are broad, with a somewhat concave edge. As much of the superfluous skin is to be taken hold of and raised as will enable the patient to open the eyelid, which circumstance is the criterion of the quantity selected for the removal being enough. The excision may then be performed with scissors, as Beer directs, or with a knife, as others may prefer; and the wound is to be closed with a suture. The slip of skin chosen for removal should not be too near the edge of the eyelid, for then the skin of the lower edge of the wound would be too narrow for the application of the suture.—(*Beer, b.* 2, *p.* 115.) Some writers refer particular cases of ptosis altogether to paralysis of the levator, and other instances to spasm of the orbicular muscle. When the disease depends on paralysis, it is mostly an effect of apoplexy, upon the relief of which its cure also depends. The treatment directed particularly against the paralytic affection of the levator, consists in frequently bathing the eye and surrounding parts with cold spring water, and rubbing the eyelid and eyebrow with the camphor liniment, to which a little of the tinctura lyttæ is added. The shower bath, bark, and other tonics are also indicated. If these means fail, an issue may be made with the moxa or potassa, between the mastoid process and angle of the jaw, and kept open two or three weeks. The cure of spasmodic ptosis, which is rather a symptom of other diseases, like hysteria, chorea, worms, &c. than a distinct affection, consists in the removal of the original complaint. However, generally speaking, anti-spasmodic medicines; blisters on the temple, or behind the ear; an issue between the mastoid process and angle of the jaw, as recommended by J. A. Schmidt, on account of some nervous ramifications of the third branch of the fifth pair, which give twigs to the eyelids lying in that situation; and fomenting and bathing the eye, eyelids, and face with a decoction of poppy-heads and cicuta; are the means which merit the consideration of the practitioner.—(See *Richter's Anfangsgr. der Wundarzn. b.* 4, *p.* 488, 8*vo.* 3*d edit. Gött.* 1802. *J. A. Schmidt, in Abhandl. der Konigl. Med. Chir. Jos. Acad. zu Wien, b.* 2, *p.* 365, 1801. *Weller's Manual, Transl. by Monteath, vol.* 1, *p.* 97, *&c.* 8*vo. Glasgow*, 1821. *G. J. Beer, Lehre von den Augenkr. b.* 2, *p.* 109, *&c.* 8*vo Wien*, 1817. *G. J. Guthrie, Operative Surgery of the Eye, p.* 41, *&c.* 8*vo. Lond.* 1823.)

[PULSATION.—(See *Abdomen.*) Mr. Loudon, of Leamington Spa, did me the favour of transmitting to me last spring, some particulars of a case where the pulsations of the aorta against a diseased liver, which had extended itself into the epigastrium, and which during life, was manifested by a well-defined tumour at the pit of the stomach, were mistaken by several of the most eminent medical men in the neighbourhood of Leamington, as indicative of an enlargement of the aorta immediately behind the stomach. Dissection proved the vessel to be perfectly sound. The frequent occurrence of such cases as explained in this Dictionary should be well remembered in practice —*Pref.*]

PUNCTURED WOUNDS. See *Wounds.*

PUPIL. When the opening in the centre of the iris is preternaturally large, and this organ more or less deprived of its power of motion, the disease is technically named *mydriasis*, which is either *symptomatic* or *idiopathic*. The first form of the complaint, as Weller observes, is exemplified in cases of hydrocephalus, hydrophthalmia, pressure on the brain from various causes, worms, amaurosis, &c. The second often presents itself as a paralytic affection of the iris; a state frequently induced by the application of certain narcotics, like belladonna and hyoscyamus. *Congenital* cases of mydriasis are also met with, as well as instances brought on by a long residence in darkness. A dilatation of the pupil may likewise be the consequence of an adhesion of the uvea to the anterior capsule of the lens. When the retina continues sensible, the inconveniences produced by mydriasis, are intolerance of light, complete blindness in the daytime, and in the end amaurotic mischief, occasioned by the irritation of the immoderate quantity of the rays of light admitted within the eye. The kind of prognosis, and the mode of treatment, must often depend entirely upon the primary affection, of which many cases of mydriasis are only symptomatic. Of course, the original disorder must always be cured, if possible. When mydriasis appears to rise from paralysis of the iris, blisters may be applied over the eyebrows, and the same remedies tried which are usually employed in other local paralytic disorders. The entrance of too much light into the eye may be moderated with shades and tubulated spectacles.

The case which is the reverse of the preceding is a preternaturally contracted, more or less immoveable state of the pupil, termed *myosis*. According to Weller, it is sometimes congenital. It is often met with as a symptom of other disorders, especially ophthalmy, inflammation of the dura mater, phrenitis, concussion of the brain, &c. Persons whose business is to be looking at small shining objects, as watchmakers, often acquire a myosis from habit, and they cannot be cured of it, unless they avoid the causes which brought it on, keep themselves in a darkish room, and use a green shade or tubulated spectacles.—(See *Weller's Manual, &c. Transl. by Monteath, vol.* 2, *p.* 54.) It is noticed by Beer, that myosis, when a sequel of ophthalmy, is less obvious than most other consequences of ocular inflammation; for though the iris is motionless, and the pupil considerably diminished, this opening is perfectly clear and black, and not drawn out of its usual position, nor its pupillary edge in the slightest degree angular. The patient, though he is continually complaining of weakness of sight, is able to distinguish (with some trouble indeed) even the smallest objects in the daytime, and in very light situations; but his sight is evidently worse in the evening, and in darkish places in the daytime; for, when both his eyes are affected, he is in the dusk nearly blind, and can scarcely find his way. Beer remarks, that almost every considerable internal ophthalmy, or iritis, however favourably the disorder may be cured, and the eyesight restored, always leaves after it more or less contraction of the pupil, which affection, though not the least portion of coagulating lymph can be perceived in the posterior chamber, is combined with a partial or complete immobility of the iris. Beer assures us, that every expedient which he has yet tried for the permanent removal of this complaint has failed, the dilatation of the pupil thus produced being but temporary. And with respect to the most powerful narcotics, he states, that in two cases they were worse than useless, as they caused a still greater contraction of the pupil, which, however, after a few hours, resumed its former diameter. Hence, this experienced oculist is disposed to set down the myosis following internal ophthalmy as an incurable complaint.—(See *Lehre von den Augenkr. b.* 2, *p.* 261, *&c.*)

The next case demanding some notice in this work is a *closure of the pupil* (*atresia pupillæ*). According to Beer's observations, there is only one exception, in which in the adult patient a closure of the pupil is not the consequence of ophthalmy, and the case here signified is termed a *collapse of the pupil*, or *synizesis pupillæ*, the causes of which are said to be, either a very considerable loss of the vitreous humour from a wound of the eye, or else a dissolved or rather disorganized state of the same humour, known under the name of *synchisis*.—(*Lehre, &c. b.* 2, *p.* 190.) Every internal ophthalmy, extending to the retina and choroides, when in its highest degree, is apt to produce a complete closure of the pupil. However, the obliteration of this opening is not the only cause of blindness; for, long before this state of the iris happens, the sight is destroyed by considerable and frequently irremediable injury of the retina and neighbouring textures, in which the inflammation is directly situated. An incomplete closure of the pupil, Beer says, is still more disposed to take place at the period when iritis passes from its first into its second stage, and syphilitic iritis is said to be particularly apt to leave after it this disagreeable consequence.—(*Vol. cit. p.* 191.) In cases of the latter description, vision is not always quite prevented, but only more or less diminished, the coagulating lymph effused in the posterior chamber having formed only a delicate, semitransparent web. However, if, in the second stage of the inflammation, such lymph should be converted into a dense membrane, with opacity of the lens and its capsule, the eye then only retains more or less perfectly the faculty of just distinguishing the light. But when, in such a case, the patient is completely insensible of the difference between light and darkness, the blindness, as in the examples mentioned above, is not owing to the closure of the pupil, or to the cataract, but to other morbid changes resulting from the same inflammation which caused the defect in the pupil itself, and capable of being ascertained by peculiar appearances in the eye. Passing over obstructions of the pupil by the unabsorbed matter of hypopium, and by the continuance of effused blood in the chambers of the eye, I come to the case next noticed by Beer, in which a closure of the pupil arises from a partial adhesion of the iris to the cornea (*synechia anterior*), and will inevitably happen, when a considerable portion of the iris, or a great part or the whole of its pupillary edge protrudes through an opening in the cornea, and becomes adherent to it. However, sometimes in these cases, the pupil becomes completely obstructed, though the protrusion of the iris is inconsiderable, and its pupillary edge not engaged in the cicatrix; a circumstance exemplified when the cicatrix over the adherent part of the iris expands very much, and has an extensive leucomatous surface, so that, though the pupil may be of considerable size, it is concealed, and vision impeded. And even when there is no adhesion of the iris to the cornea, no synechia anterior, as it is termed, and no distortion of the pupil, a large dense cicatrix of the cornea may obstruct vision by lying exactly over that aperture. Lastly, as Beer has explained, the greater part of the cornea may be in an opaque, spoiled condition, so that the healthy iris can be discerned only at certain points behind its circumference, no vestige of the pupil itself being distinguishable; and such concealment of this opening may be either combined or not with a partial adhesion of the iris to the cornea. In such cases, the patient can frequently perceive the light very well.—(*B.* 2, *p.* 194, 195.)

From what has been stated it is manifest, says Beer, that in many cases of atresia iridis the prognosis must be highly unfavourable, and that no attempt to form an artificial pupil should ever be made, when the patient's blindness proceeds from other causes besides the imperforate state of the iris. Such an operation, Beer observes, can only be proper when the blindness is entirely owing to the closed or concealed state of the pupil; when the different degrees of light can be plainly distinguished; when the case is uncomplicated with any disease of other important textures of the eye, capable of rendering the manual proceedings difficult or impracticable; when the eye has been for a long time perfectly free from inflammation; when the patient is healthy, without any tendency to scrofula, syphilis, or gout; and both his eyes are completely blind.—(*B.* 2, *p.* 196.) Some questions may be entertained respecting this absolute prohibition of the operation in unhealthy subjects, because the line between the degrees of health and disease, requisite for the success of the operation, is difficult to specify, and gout, syphilis, and scrofula are often vague expressions. Yet, no doubt can exist, I think, about the propriety of Beer's advice, never to attempt the formation of an artificial pupil, when the patient enjoys vision with one of his eyes; for, when the new open-

ing is made, as it is not in the axis of vision, the sight is confused in the other eye, unless the imperfect eye be kept closed; and the operation can never be done without exposing the patient to the risk of more or less inflammation in the eye, which is at present so useful to him. Whatever may be the differences of opinion about operating in cases of single cataract, I believe that all surgeons will unanimously join Beer in the foregoing advice, respecting the imprudence of attempting to make an artificial pupil when the patient can see with one eye.

When vision is totally lost in one eye, and materially impaired in the other, Mr. Guthrie very judiciously observes, that the question, whether an operation ought to be performed or not, is important; for if the patient still enjoys sufficient power of vision to guide himself, the surgeon would be more than hardy who would put that portion of the faculty of sight in jeopardy by attempting an operation: which may fail, however skilfully done. Yet Mr. Guthrie does not absolutely denounce the operation: he adds, "In such circumstances, the operation should not be attempted upon any grounds, unless the case is so simple as to require only an opening in the cornea, and the removal of a portion of the iris, for the purpose of enlarging the natural pupil. If the patient cannot see sufficiently well to guide himself, the conditions are very essentially altered, since an unsuccessful operation involves the loss of very little, whereas much is to be gained by the successful issue of it. Where opacities in the centre of the cornea occasion the impediment to vision, it is prudent to dilate the pupil beyond the edge of the opacity, by the daily application of the belladonna, which may possibly enlarge the sphere of vision so as to supersede, in a doubtful or dangerous case, the necessity of an operation."—(See *Operative Surgery of the Eye*, *p.* 444.)

Beer represents the event of the operation as being very uncertain, when the patient cannot plainly discern the various degrees of light; when the cornea is affected with leucoma, or scarred and spoiled nearly to its very circumference; when there is only a partial staphyloma of it; or the constitution is unhealthy, or impaired by the effects of former attacks of scrofula, syphilis, or gout. Lastly, Beer sets down the operation as certainly useless, or even as likely to cause an entire destruction of the eye, when the patient is quite insensible of light; when the iris and neighbouring textures, such as the corpus ciliare, corona ciliaris, the membrane of the vitreous humour, this humour itself, and the blood-vessels of the organ, are in a morbid state, or the whole eyeball manifestly in a preternatural condition. However, an opacity of the lens, and its capsule, even when the latter is completely adherent to the uvea, forms no prohibition to the formation of an artificial pupil, though it is a circumstance that has great weight in the selection of the method of operating.—(*Beer*, *b.* 2, *p.* 197.)

The following information, from the same source, is highly important to the practitioner: the morbid state of the iris, and other adjacent textures of the eyeball, prohibiting the operation, may be known by the annexed circumstances. Together with the smaller circle of the iris, the larger one is strikingly changed, in respect to its colour, its consistence, and its layers. Its radiated fibres are collected into dark-blue or blackish fasciculi, between which there is an appearance of empty interspaces, produced by the indentations of the iris, and actually semitransparent, in consequence of the tapetum of the uvea having always been in these cases more or less annihilated by the previous inflammation. Around the cornea the sclerotica seems bluish, or rather of a smutty grayish-blue colour; and sometimes certain points of this membrane are protuberant. The morbid states of the whole eyeball, which may complicate the atresia iridis, and render the operation not only useless but hazardous to the preservation of the eye, are its dropsical enlargement (see *Hydrophthalmia*); its atrophy; its preternatural firmness, from a general varicose affection of its blood-vessels; and its morbid softness, from a disorganization of the vitreous humour.—(*Beer*, *vol. cit. p.* 198.)

Before proceeding farther into the subject, I think it will simplify it very much to state, that numerous as the plans are of making an artificial pupil, if we except the occasional practice of forming a kind of artificial prolapsus of the iris, in order to change the position or shape of the imperfectly-closed pupil, they may all be classed into three principal methods. 1. The simple transverse, perpendicular, or otherwise-directed incision in the iris, now termed *corotomia*, performed either through the sclerotica or the cornea. 2. The excision of a piece of the iris, technically named *corectomia*. 3. The separation of a part of its circumference from the ciliary ligament, called in the language of oculists *corodialysis*, with which the last method, or the operation of *corectomia*, is combined in the plans suggested by Asselini and Reisinger. The excision of a portion of sclerotica close to the cornea, with the view of forming an inlet for the rays of light to the retina, as proposed by Autenrieth, when the cornea is entirely opaque, may be considered a hopeless proceeding. With respect also to the three other methods, it is now well understood by all impartial surgeons, that the choice of them must depend upon the particular circumstances of the case, and that here it would be as absurd to think of employing in all instances only one plan, as to have the idea of extending the same principle to all the forms and varieties of cataract.

When the thing is possible, it is considered by Beer most advantageous to make the artificial pupil rather towards the inner canthus; though others express a preference to the centre of the iris. But, as he very truly remarks, since the new opening must be where the cornea is transparent, the operator is frequently obliged to form it either below, or towards the temple, or quite above; for there is often only just room enough left at one point for conducting the necessary manœuvres with any degree of precision.

The following remarks by Mr. Guthrie I consider interesting: "An opening must be made in the iris, of an extent equal, at least, to the natural size of the pupil when moderately dilated; for, if it be less, there will not be sufficient room for the rays of light to act with effect on the retina in a moderate light; and it must not be forgotten, that the artificial pupil never acquires the motions of dilatation and contraction, so eminently useful in the natural one. It should not, on the other hand, be too large; because it would prove detrimental to vision, by admitting too many rays of light to the retina. It should resemble the natural opening in form as nearly as possible; for there cannot be a doubt of the advantage derived in man from a circular pupil, where the axis of vision is directly forwards; and, although an artificial one is seldom made in a circular form, and in the centre of the iris, still that process will be the best the result of which most nearly resembles the natural state.

"When an artificial pupil cannot be made in the centre of the iris (from whatever cause), the other parts of it are eligible in the following order. 1. The inferior part of the iris inclining inwards. 2. The internal, a little below the transverse diameter of the eye. 3. The inferior and external; the upper part being the least eligible, from the eyelid covering that portion of the cornea in the natural state of the eye."—(*Operative Surgery of the Eye*, *p.* 442.)

Mr. Guthrie agrees with Beer, that the place in which the iris is to be perforated generally depends more on the transparency of the cornea than the choice of the operator. It is also remarked, that a small artificial pupil, at the lower part of the iris, is infinitely more valuable than a large one at any other, which, in the natural state of the eye, is covered by the eyelid, or much out of the axis of vision. If the state of the cornea will permit it, Mr. Guthrie says, a sound part of the iris should be selected.—(*P.* 443.) He considers the external and internal margins of the iris, immediately on a line with the central transverse diameter, particularly unfavourable for the method in which the iris is separated from the ciliary ligament, because there the long ciliary arteries enter, and the attachment of the iris is firmer than at other points.

Cheselden first devised a section of the iris, for the purpose of forming an artificial pupil. He proposed the introduction of a couching needle, with a sharp edge only on one side, through the sclerotica, about half a line from the cornea, into the posterior chamber. After the iris had been perforated towards the external angle, and the point of the needle then pushed through the anterior chamber, as far as that side of the iris which is nearest the nose, the edge was turned backwards, and the instrument withdrawn, so as to make a transverse division of that membrane.

The account of the proposal, given by Cheselden himself in the *Philosophical Trans. for* 1728, is very incomplete; and according to Mr. Guthrie, he did not actually perform the operation on the person whose history he there relates, but only annexed to it an account of a particular operation which he considered worthy of record: a circumstance which, from not being attended to, has been the source of considerable errors.—(*Operative Surgery of the Eye, p.* 395.) Morand, when he was in London, saw Cheselden form an artificial pupil; but the process, as described by Morand, differs from the above, inasmuch as the needle passed as far across the posterior chamber as two-thirds of the iris, when its edge was turned towards this membrane, which was thus cut, and as much of it divided, in withdrawing the instrument horizontally, as left an artificial pupil of an oblong form.

Janin performed Cheselden's method, as described by Morand, on two subjects with the utmost care possible, but not the smallest benefit followed: for after the subsidence of the symptoms produced by the operation, the transverse section made in the iris by the edge of the needle reunited.—(*Mém. sur l'Œil.*) Mr. S. Sharp also saw a failure from the same cause.—(*On Operations, chap.* 29.)

An accident occurred to Janin, in the act of extracting a cataract; viz. he included the iris together with the cornea, in Daviel's scissors, and cut it perpendicularly, and the division remained permanent. This led him to propose a perpendicular incision as the best expedient for making an artificial pupil. His plan consisted in opening the cornea, as is practised for the extraction of the cataract, and in dividing the iris perpendicularly with scissors near that part of the pupil which is next to the nose; for he affirms, that he has seen strabismus result from making the section towards the external side, on account of the too great divarication of the optical axes.

Although the practice of making an incision in the iris or corotomia is severely disapproved of by Beer, who stat that it admits of being practised only in very few cases, and is rendered quite unnecessary by what he denominates the two other better plans (*b.* 2, *p.* 199), it is still considered by some men of experience as having recommendations, and they have therefore endeavoured to improve it. However, it will only be in my power to notice in this work a few of its modifications.

In 1812, Sir W. Adams recommended the revival of Cheselden's method of forming an artificial pupil, with the difference of using for the purpose a particular sort of knife. "With a cataract needle (says this oculist) I could not cut through the iris by a gentle force; and if I ventured to apply a greater force, the iris separated from its attachment to the ciliary ligament, which rendered all farther attempts to effect a central aperture useless. The same accident appears to have happened to Mr. Sharp in his trials of this operation. In the hopes of procuring an appropriate instrument, I twice went to London, at the interval of a few months; but though I described to different instrument-makers the purposes for which it was intended, still I could only procure the needle which cuts on one edge, and the spear-pointed knife of different sizes, described by Cheselden. At length it occurred to me that the curved edge of the common dissecting scalpel was well adapted to cut with facility. I therefore, when in London a third time, got a small knife made, two-thirds of an inch in length, and nearly a line in width, with a straight back, sharp point, and a curved edge, which cuts back towards the handle for about three lines."—(*Adams's Pract. Obs. on Ectropium, &c. p.* 30.) According to this writer, *in all cases where there is no crystalline lens, and the cornea is free from opacity, the division of the iris should be made in the centre*, and should extend across at least two-thirds of its transverse diameter. In a later work, however, he states, that experience has convinced him, that so extensive a division of the iris is unnecessary for the prevention of the reunion of this membrane, and that a cut through one-third of its diameter is sufficient. The eye being gently fixed, either with the finger of the assistant, who supports the upper eyelid, or with a concave sort of speculum placed under the upper eyelid, the artificial pupil knife is to be introduced through the conts of the eye, about a line behind the iris, with its cutting edge turned backwards The point is next to be brought forwards through the iris, somewhat more than a line from its temporal ciliary attachment, and cautiously carried through the anterior chamber, until it has nearly reached the inner edge of that membrane (or as is expressed in a later description), "until it has traversed more than two-thirds of the width of the iris," when it should be almost withdrawn out of the eye, gentle pressure being made with the curved part of the cutting edge of the instrument against the iris, in the line of its transverse diameter. If in the first attempt the iris should not be sufficiently cut, the point of the knife is to be again carried forwards, and similarly withdrawn, until the incision is of a proper length. After the operation, the eye is to be covered with a plaster of simple ointment, and the patient put into bed, with his head raised.—(*P.* 36, 37.) When the closure of the pupil is attended with a cataract, the primary steps of the operation are the same; but Sir W. Adams takes care also to cut the cataract into pieces, some of which he brings forwards into the anterior chamber, while others he leaves in the opening of the iris, where they at first serve as a plug, hindering union by the first intention (*p.* 38), and are afterward absorbed. For an account of his particular methods for all the various complications of cases, the reader must consult his publications, where many successful examples of the operation are recorded.

That Cheselden's method ought not to be entirely rejected, there can now be no doubt. Like all other modes of forming an artificial pupil, it certainly does not merit exclusive preference. In addition to the testimony of Sir W. Adams, we have that of Mr. Ware, to prove that Cheselden's operation frequently succeeds. When the pupil had become closed, after an unsuccessful extraction of the cataract, Mr. Ware in several instances made a new pupil agreeably to Cheselden's mode, with the most perfect success. "The fibres of the iris retracted as soon as they were divided, and left the pupil very nearly of its natural size. Its shape was not quite round; but the sight was immediately restored, and to so great a degree as to enable the patient, by the help of suitable convex glasses, to see distinctly both near and distant objects, neither pain nor inflammation being consequent to the operation."

Where there is a prolapsus of the iris, through a breach of the cornea, involving more or less of the pupillary margin, Mr. Travers considers Cheselden's method the most applicable; viz. "the transverse division of the stretched fibres of the iris, and which, if the section be made in front of the membrane, *i. e.* from before backwards, admits of no improvement. The edges of the section instantly recede and form an excellent pupil." However, he afterward adds, "that a partial adhesion of the pupillary margin may be combined with a healthy lens. In this case, the removal of the free border of the pupil, drawn by means of forceps through an incision in the cornea, will be preferable, on account of preserving the transparency of the lens."—(*Synopsis of the Diseases of the Eye, p.* 343.)

In a modern work, Professor Maunoir, of Geneva, has published a very successful case, in which an artificial pupil was formed and a caseous cataract extracted. "I operated (says he) on the right eye in the following manner. The patient being seated on a chair, and having the head inclined upon a cushion, I placed myself behind him, and, with the fore-finger of the left hand confining the upper eyelid, while an assistant depressed the lower, I made with the right hand a semicircular incision in the lower and external part of the cornea. This incision occupied a full third of the circumference of the membrane. On re-opening the eye, the iris was seen projecting a little from the wound in the cornea. I replaced it with the blunt point of my scissors. Introducing the two blades closed into the anterior chamber, and then opening them, I caused the pointed blade to penetrate the iris, leaving the blunt blade between that membrane and the cornea; then closing the scissors, a perpendicular incision of the iris resulted, describing a little more than half the chord of an arc of two-fifths of the circumference of the iris traced on the side of the temple. The first incision not having occasioned the formation of a pupil of the necessary size, I introduced the scissors into the iris a second time a little obliquely; and immediately the pupil appeared of a satisfactory form

and size, but exhibiting the crystalline entirely opaque. The second stroke of the scissors had divided the capsula: I therefore introduced the small curette, in order to endeavour to destroy what adhered of the crystalline to the shrunk and contracted circumference of the old pupil. This attempt did not succeed. Lastly, I effected a passage of a portion of the opaque lens, by means of a slight pressure with a large scoop, exercised on the lower part of the globe of the eye. The crystalline, which was of a cheesy consistence, came out with the greatest ease, and though it was not entirely removed, yet a sufficient quantity was discharged to leave the artificial pupil of a most perfect black. This new pupil was on the side of the temple; and at the exterior and lower part of the iris."—(See *Med. Chir. Trans. vol.* 7, *p.* 305, *et seq.*) In this communication are also two other cases, in which Maunoir operated with success, though they were complicated with cataracts and adhesions of the lens to the iris. In some remarks annexed by Scarpa to the preceding account, the latter expresses his opinion, that it is not necessary to be scrupulous whether the crystalline be partly or entirely opaque, whenever the capsule is opaque and adheres to the iris behind the edge of the interior and enclosed pupil. "In this case only one remedy can be pointed out, namely, the removal of the opaque adherent capsule, and consequently of the crystalline, whether it be transparent or opaque. In the second place (says Scarpa), I think there is no reason to doubt, that in similar cases, it is advisable to make an incision upon the iris, proportioned to the size of the body to be extracted, rather than to make it small, which obliges the operator to divide the crystalline and the capsule, with the intention of extracting a part and of abandoning the rest to the powers of absorption. Thirdly: I would establish as a fundamental principle, in similar cases, that after the complete extraction of the crystalline, with its opaque capsule, by means of the least possible introduction of the instruments, the artificial pupil ought not to be too near the incision in the cornea, and consequently not too near the cicatrix occasioned by it."—(*P.* 317.) Scarpa then recommends a particular method of operating in cases where there are cataracts: after having made, in the manner of Wenzel, a transverse incision in the iris and in the cornea, he would introduce Maunoir's scissors, blunted at both points, into the anterior chamber of the aqueous humour, and make an incision in the iris, diverging from the cut made with the knife. The aperture thus made, Scarpa thinks, would be large enough for the easy passage of the opaque lens.

Among other late opinions professed by Scarpa, we find the following: that no instrument is so proper as the scissors for making an incision in the iris; that when the case is not complicated by cataract, a very small wound in the cornea is sufficient; that the formation of a triangular edge in the iris, by means of a double incision with the scissors, is the most easy and least painful of all the methods hitherto proposed for obtaining a *permanent* artificial pupil; and, lastly, that specks of the cornea present no obstacle, because the artificial pupil may be made opposite the transparent part of that membrane.—(*Med. Chir. Trans. vol.* 7, *p.* 320, 321.)

As I have already noticed, the contraction of the natural pupil is sometimes occasioned by the iris being stretched towards some point of the cornea to which it is adherent. This state, as Scarpa observes, is most frequently accompanied with partial opacity of the cornea around the adhesion, or prolapsus of the iris, as well as with opacity of the lens and its capsule. At other times, however, these internal parts preserve their natural transparency, notwithstanding the deviation of the natural pupil. In the latter case, the pupil, though removed from its situation, is not in reality obliterated, but merely very much contracted, and incapable of admitting the quantity of light necessary for vision, especially if the opposite part of the cornea be slightly opaque. In such an example, Scarpa recommends making a small incision in the cornea at the most commodious part, when with Maunoir's scissors closed, and constructed with little buttons at the ends of both the blades, an endeavour is to be made to break the adhesion existing between the iris and the cornea. If this can be effected, the natural pupil generally recovers its former situation and size; but if the adhesion be very firm, Scarpa introduces one of the blades within the contracted pupil, behind the posterior surface of the iris, until the other blade has reached the confines of the cornea with the sclerotica. The iris is then to be divided in the form of the letter V, without at all injuring the capsule or lens, both of which are transparent.—(*On Diseases of the Eyes*, *p* 384, *ed.* 2, *transl. by Briggs.*) When, after extraction of the cataract, the pupil has been dragged down in this manner by adhesion to the lower third of the cornea, the upper two-thirds of which are transparent, Dr. Monteath, of Glasgow, has succeeded five times in forming an artificial pupil, and restoring vision, by making a small opening in the upper and outer part of the edge of the cornea, capable of admitting Maunoir's eye-scissors, with which the overstretched fibres of the iris are to be cut across by one simple incision three lines in length. The cut edges instantly recede and leave an oval pupil of sufficient size.—(See *Weller's Manual*, *vol.* 2, *p.* 70.) In the cases above specified by Scarpa, Sir Wm. Adams, instead of performing corotomia, endeavours to separate the iris from the cornea, and then to alter the position of the pupil by drawing it towards that part of the cornea which has remained transparent. For this purpose he punctures the cornea about one line in front of the iris, separates the adhesion, and then makes the disengaged portion of the iris protrude through the puncture and leaves it there, even using the forceps, if necessary, for drawing it out as far as is deemed necessary for its being securely fixed. This method is disapproved of by Scarpa, because a second prolapsus of the iris in the same eye appears to him a very serious disease, and rather calculated to increase the opacity of the cornea, and augment the contraction of the pupil, than afford relief.

According to Beer, in the excision of a portion of the iris, *corectomia* is particularly indicated in all cases in which there is a sound transparent lens, as in many examples of synechia anterior, concealment of the natural pupil by a central opacity of the cornea, &c. Beer admits, however, as an exception, the instances in which the transparent portion of the cornea is so small that no opening can be made in it with the knife large enough to permit the iris to be taken hold of with a small hook or forceps, and a piece of it cut out above the ciliary processes.—(*B.* 2, *p.* 200.) The reason here given does not appear to myself very strong, because it may be asked, why not acquire more room by cutting a portion of the opaque part of the cornea? Weller assigns a better reason against corectomia, viz. when he refers to the risk of a sufficient piece of the cornea not being left transparent, opposite the new pupil after the cicatrization of that membrane.—(*Vol.* 2, *p.* 65.) Beer farther states, that corectomia may be performed in cases of atresia iridis consequent to the operation of extracting the cataract, when the surgeon is certain that no coagulating lymph, effused during the previous inflammation in the posterior chamber, reaches above the lesser circle of the uvea, or is conjoined with opacity of the remaining capsule of the lens. The first state may be learned from the singular colour and form of the greater ring of the iris; the second, from the very indistinct manner in which the patient is sensible of the different degrees of light.—(*Beer*, *b.* 2, *p.* 200.)

The excision of a piece of the iris, says Beer, requires the preliminary formation of a flap in the cornea, one line in length, with the cataract-knife, and as close as possible to the sclerotica, so that no subsequent opaque cicatrix may interfere with the success of the operation. The second part of the business, viz. the excision of a piece of the iris, must be done in three ways, according to circumstances. 1. The iris may not be any where adherent to the cornea, in which case, after an opening has been made in the latter membrane, the iris is propelled out between the edges of the wound by the aqueous humour, yet left in the posterior chamber, which opportunity the surgeon must immediately avail himself of for taking hold of the projecting piece of the iris with a very fine hook, and cutting it off with Daviel's scissors. The remainder of the iris is instantly retracted behind the cornea, and a well-formed pupil is immediately seen. 2. Only the part of the edge of the pupil may remain not adherent to and drawn towards the cornea, where it is intended to form the artificial pupil; a state best ascertained by a lateral inspection of the eye. In this case, after opening the cornea, Beer says, the operator

is directly to introduce a small hook between the iris and cornea, so as not to injure either of these parts with its point, and he is then, with the instrument directed obliquely, to get hold of the pupillary edge of the iris, and, while the iris is drawn out between the edges of the incision, the projecting piece is to be cut off with Daviel's scissors. Thus the natural pupil is to be extended behind the transparent part of the cornea towards the edge of this membrane. 3. The pupillary edge of the iris may be adherent to the cornea exactly in the situation where the artificial pupil is to be formed: in this case, Beer directs the iris to be taken hold of at its greater circle with the hook, or (if this should tear its way out) with a pair of fine-pointed forceps with teeth drawn out between the edges of the wound, and the point of the cone thus produced cut off somewhat within the edges of the wound, as drawing the iris farther out might tear it and have a prejudicial effect. In all these cases, says Beer, the undiseased lens and its capsule will not be injured if the patient keep tolerably steady, and the operator have already acquired dexterity in the extraction of the cataract. The operation being finished, the subsequent treatment is like that generally adopted after the extraction of the cataract.—(See *Cataract.*) When corectomia is to be performed for a closure of the pupil, consequent to extraction of the cataract, Beer particularly recommends the forceps to be used, though he adds, that such operation is applicable only when the remaining capsule has not been spoiled by inflammation, and the quantity of lymph in the posterior chamber is not so great as to reach above the lesser circle of the uvea.

The only other species of corectomia which I deem it necessary to notice, is what was proposed, in the year 1811, by the late Mr. Gibson of Manchester. It is described as follows: "The first step of the operation is to secure the eyelids, as in the operation for extracting a cataract. A puncture is then to be made in the cornea, with a broad cornea-knife, within a line of the sclerotica, to the extent of about three lines. All pressure is now to be removed from the eyeball, and the cornea-knife gently withdrawn. The consequence of this is, that a portion of the aqueous humour escapes, and the iris falls into contact with the opening in the cornea, and closes it like a valve. A slight pressure must now be made upon the superior and nasal part of the eyeball, with the fore and middle finger of the left hand, till at length, by an occasional and gentle increase of the pressure, or by varying its direction, the iris gradually protrudes, so as to present a bag of the size of a large pin's head. This protruded portion must be cut off with a pair of fine curved scissors, and all pressure at the same time removed: the iris will then recede within the eye, and the portion which has been removed will leave an artificial pupil more or less circular."—(*Gibson on Artificial Pupil, &c. Lond.* 1811.) Such was this surgeon's mode of operating, when the closure of the pupil was attended with central opacity of the cornea, uncombined with adhesions. The effect of a slight adhesion of the inner border of the iris to the cornea will be, to prevent the protrusion of the first of these membranes through the puncture in the cornea, which protrusion so much facilitates the operation. In this case, a portion which does not adhere must be drawn out with a small hook, and then removed. Sometimes the adhesion may be separated at the time of making the puncture, and then the iris will protrude. When the whole or greater part of the inner border of the iris is involved in adhesions to the cornea, these must be separated with the cornea knife after making the puncture, and the iris may then either be drawn out with the hook, or a portion of it be removed by means of very minute scissors. In every case, however, the removal of a portion is essential to success.

When a cataract is known to exist, Mr. Gibson recommends it to be depressed, or broken to pieces with the needle, before making the artificial pupil; and when the whole cornea is transparent, he directs a flap to be made in the centre of the iris with the cornea-knife, and then cut off with the iris scissors.—(*Gibson, op. cit.*)

Coredialysis, or the mode of forming an artificial pupil by detaching a portion of the iris from the ciliary ligament, is said to have been devised by Ad. Schmidt and Scarpa about the same time, and has been variously modified by Reisinger, Langenbeck, Himly, Graefe, and others.—(*Weller on Diseases of the Eye, vol.* 2, *p.* 65.) According to Beer, this plan of operating is indicated, first, only when the coagulating lymph, effused in the posterior chamber after the extraction of the cataract, or reclination (see this word), reaches from above the lesser circle of the uvea towards the ciliary processes; a circumstance which may be known by the considerable change of colour in the greater circle of the iris, and by the indistinct manner in which the patient perceives the light. Secondly, when the uvea is every where adherent to a secondary capsular cataract, or capsulo-lenticular cataract, or the closure of the pupil has been occasioned by a purulent or bloody cataract. Whenever the attempt is made in these last cases, however, the patient should be capable, as he sometimes is, of plainly discerning the light. Lastly, coredialysis is sanctioned by Beer, when the cornea is every where incurably opaque, excepting so small a part of it that it could not well be opened for the excision of a portion of the iris.—(*B.* 2, *p.* 203.)

When the closed pupil is the result of inflammation from an injury, the lens has been absorbed, and the anterior capsule, or both the anterior and posterior, are thickened and firmly attached to the iris with only an indistinct perception of light, and a discoloration of the lesser circle of the iris, indicating a deposition of lymph behind it, Mr. Guthrie sets down coredialysis as the proper operation; "for the formation of a triangular opening by the scissors would not be easily accomplished to a sufficient extent; and the simple division of the central part of the iris would in general be ineffectual, in consequence of the thickened capsule preventing the necessary retraction of the fibres of the iris."—(*Operative Surgery of the Eye, p.* 466.)

The feeble union of the iris with the ciliary ligament, and consequently the greater facility of detaching its edge from that ligament, with which it is connected, than of lacerating its body, induced Scarpa to try a new method of forming an artificial pupil when the natural one had become too much contracted, or quite obliterated, after the extraction or depression of the cataract. His method of operating consists in detaching, by means of a couching needle, a certain extent of the circumference of the iris from the ciliary ligament, without dividing the cornea. The attempt met with success.

The patient being seated and supported, as if he were about to have the operation for the cataract performed, a straight slender couching needle is to be introduced through the sclerotica, at the external angle of the eye, about two lines from the union of this membrane with the cornea; and its point is to be pushed as far as the upper and inner edge of the iris; in other words, as far as that side of the iris which is nearest the nose. The needle advances nearly to the ciliary ligament, and the surgeon perforates the interna edge of the iris at its upper part, so that the point of the instrument scarcely appears in the anterior chamber, because that part of it being very narrow, the point of the instrument, however little it advance beyond the iris, would enter the substance of the cornea. The moment the needle appears in the anterior chamber, the instrument must be pressed on the iris from above downwards, and from the internal towards the external angle, so as to bring it in a parallel line to the anterior surface of the iris, for the purpose of detaching a portion of the edge of this membrane from the ciliary ligament. This separation being effected, the operator must depress the point of the needle, in order to apply it to the inferior angle of the slit that he has begun to make. Then the aperture may be enlarged at pleasure, by pushing the iris towards the temple, and withdrawing the needle from before backwards, parallel to the anterior surface of the iris and the greatest axis of the eye. If, when this detachment has been accomplished, no opaque body appear at the bottom of the eye, the needle is to be withdrawn altogether. If any portion of opaque capsule left behind after the depression or extraction of the cataract should afterward advance, and present itself in the vicinity of the new pupil, the little opaque membrane must be reduced to fragments, and pushed through the artificial opening into the anterior chamber, where, Scarpa says, they will in time be dissolved and absorbed.

This separation of the iris from the ciliary ligament invariably occasions an extravasation of blood, which

always renders the aqueous humour more or less turbid; but the turbidness is afterward absorbed, and the eye recovers its original transparency.

The patient, says Scarpa, complains during the operation of a vast deal more suffering than at the time when he undergoes the extraction or depression of a cataract. It cannot be otherwise; for in detaching a part of the edge of the iris from the ciliary ligament, some filaments of the ciliary nerves, which proceed to be distributed to the iris, must at least be dragged or lacerated. However, on the whole, the symptoms consequent to this operation were neither obstinate nor fatal in the two cases which Scarpa has seen. From some experiments made on the dead subject, Scarpa thinks the curved needle which he uses for the depression of the cataract, would also be better than the straight one for making an artificial pupil.—(*Scarpa sulle Malattie degli Occhi, capo* 16.)

The celebrated Ad. Schmidt performed coredialysis with a lancet-pointed curved needle, which was introduced through the sclerotica into the posterior chamber, with its concavity towards the uvea. Its point is to pass as far as the portion of the ciliary ligament, where it is designed to make the artificial pupil. The iris is then to be pierced from behind forwards, about the fourth part of a line from the ciliary ligament, from which it is to be separated, the surgeon taking care at the moment to catch well hold of the iris with the point of the instrument, which is then to be withdrawn a little from the eye. If the new pupil should not be now large enough, the iris is to be again hooked with the needle near the ciliary ligament, and the opening enlarged at its upper or lower angle, as may appear most advantageous. This plan is said to be advisable when the whole cornea is opaque, excepting a small spot.

When, however, the diseased state of the cornea does not forbid it, Beer and Schmidt very properly recommend the needle to be introduced into the anterior chamber, and the iris thus separated from the ciliary ligament; a plan which, as Weller observes, has proved more successful than the preceding method. In both modes, the lens will be pushed away from the new pupil by the movement of the needle, so that whether it be opaque already, or become so afterward, vision will not be obstructed by it.—(See *Beer's Lehre, &c. b* 2, *p.* 204—206; *and Weller's Manual, transl. by Dr. Monteath, vol.* 2, *p.* 66, *&c.*)

With the view of removing all risk of the new opening becoming closed again, Reisinger forms an artificial pupil by making a small incision in the cornea, and introducing a minute double hook which opens and shuts like a pair of forceps. After passing the hook closed into the anterior chamber as far as the greater circle of the iris, he turns the points of both the small hooks towards this membrane, then opens the instrument a little, and hooks hold of the iris, which is to be separated from the ciliary ligament, when the instrument is to be shut again, and the part of the iris taken hold of drawn a little through the opening of the cornea, where it adheres, and cannot recede again towards the ciliary ligament.—(See *Darstellung eines neuen Verfahrens die Mastdarmfistel zu unterbinden, und einer leichten und sichern methode künstliche Pupillen zu bilden.* 12*mo. Augsburg*, 1816.) Under certain circumstances, however, as there may be difficulty in drawing the iris through the cornea, or apprehensions may be entertained of the opacity of the cornea being increased by the protrusion and adhesion of the iris (the great consideration unquestionably against this method), Reisinger approves of obviating the chance of the new opening being closed again, by removing a part of the iris after its detachment from the ciliary ligament; a combination of *coredialysis with corectomia.* Were I a patient, and coredialysis were deemed most applicable to the circumstances of my case, I should dispense with any excision of the iris, preferring the chance of the new opening being permanent to the dangers of too complicated and protracted an operation.

Langenbeck is the inventor of an instrument for the formation of an artificial pupil: it is a silver tube, to one end of which is attached a very small gold one, containing a minute hook, capable of being moved backwards or forwards to the extent of only two lines, by means of a spring in the silver tube. The following is the account of Langenbeck's method, as extracted by Mr. Guthrie from his writings. "A very small opening is to be made in the cornea, in order that the iris, when brought out, may not recede. The hook enclosed in the golden tube (to prevent its bending from its tenuity), is to be directed to the spot where the iris is to be laid hold of. The hook is then to be pushed out by the spring to the extent of one line, which will be sufficient to enable it to penetrate the iris. As soon as the hook is affixed, it is to be allowed to recede to its usual place in the golden tube, drawing with it the iris, which will be caught between it and the end of the tube, something in the manner of a pair of forceps. As soon as the hook begins to recede, a small black spot will be seen at the edge of the iris from its incipient separation; and care should be taken to insert the hook at or even under the edge of the sclerotica, and as near as possible to the ciliary processes. The hook must recede gradually, the finger being kept steadily on, and moved slowly, with the knob regulating the spring in the silver tube. As the chance of tearing off a part of the iris is proportionate to the distance it has to be drawn out, the opening is to be made as near as possible to the spot where the separation is to be effected, taking care that the pupil shall be large enough, so that the prolapsed iris, and subsequent opacity of the cornea, cannot obstruct the entrance of the rays of light. The great advantage of this instrument, in Langenbeck's opinion, is, that the separation is effected, by means of the spring, more gently and gradually than by the finger alone; so that if a commencement of the separation be effected, the completion of it is certain, without any risk of tearing the iris. As soon as the hook has receded to the golden tube, carrying with it the iris, the whole instrument is to be gently withdrawn, moving it slowly up and down, in order to loosen the upper and lower attachment of the iris; for this membrane may be torn, if there has been much previous inflammation, or if direct force be employed in withdrawing it. The instrument always keeps its hold as firmly as the best forceps, and with much more advantage, for it occupies less space, and enables the operator to make the incision in the cornea small, on which the correct strangulation of the iris depends. In all his operations, the capsule of the lens has never been injured by this instrument, which he considers another advantage, and he conceives that it may be used through the sclerotica without rendering the lens opaque, as by the methods of Scarpa and Schmidt." (The latter author, however, as I have explained in this article, did not operate through the sclerotica when the lens was transparent.) When the cornea is transparent only at its outer edge, Langenbeck sometimes performs excision; but when this membrane is opaque opposite the natural pupil, he opens the cornea near the edge of the sclerotica, and if the iris will not protrude, he takes hold of its pupillary edge with the hook, and draws it between the lips of the wound, where he leaves it strangulated.—(See *G. F. Guthrie on Artificial Pupil, p.* 63, *&c.* 8*vo. Lond.* 1819; *also Langenbeck's Neue Bibl. b.* 1, *p* 1, 454 *and* 676, 8*vo. Hanover*, 1817-19, *and b.* 2, *p.* 13 *and* 106, *where he answers some objections made to his instrument by Schlagintweit.*) Doubtless, one cause of the failure of many operations for artificial pupil is one to which Mr. Guthrie has adverted, viz. the omission to keep down the subsequent inflammation of the iris and adjacent textures by the timely employment of the lancet, and other antiphlogistic measures. On this subject, however, I need not here dwell, as the proper treatment is already described in that part of the article *Ophthalmy* which refers to iritis. Consult *Cheselden, in Phil. Trans. for* 1735, *p.* 451, *&c. Sharp's Operations, chap.* 29. *Janin, Mém. sur l'Œil. PUS. (From πύον, matter.) The fluid formed by the process of suppuration.—(See *Suppuration.*)

Q

QUININE, SULPHATE OF. This valuable preparation of bark, which is now beginning to be prescribed in a large number of surgical cases where loss of appetite and great debility are present, may be exhibited in doses of from one to five grains, three or four times a day, according to circumstances. As its solubility in water is increased by an excess of acid, one drop of sulphuric acid is frequently added for every grain of quinine. When, however the circumstances of the case render it advisable to dispense with the acid, the sulphate of quinine may be prescribed without it in any aromatic water, like the aqua carui, or in the form of pills, either by itself or combined with opium, blue pill, squills, the extractum conii, or such other medicines as circumstances may require. It may also be given to children, mixed with syrup. Other preparations are the wine and tincture.

R

RACHITIS. (From ῥάχις, the spine of the back, because the disease was once supposed to depend on disease of the spinal marrow.) The rickets. See this word.

RANULA. (Dim. of *rana*, a frog.) A tumour under the tongue, arising from an accumulation of saliva and mucus in the ducts of the sublingual gland. The term has been derived either from an imaginary resemblance of the swelling to a frog, or from the disease making the patient, as it were, croak when he attempts to articulate. Such writers as have treated of this disease, before it was known that the parts affected by it were destined for the secretion of the saliva, could have no accurate notions of its true nature. Celsus is supposed to have alluded to the ranula, in the fifth section of his seventh book, where, after treating of the diseases of the tongue, he introduces the following passage: *sub linguâ quoque interdum aliquid abcedit, quod fere consistit in tunicâ, doloresque magnos movet.* The latter circumstance, however, renders it probable, that some other affection was signified, as a ranula is rather attended with a sense of restraint, than of pain. Fabricius ab Aquapendente and Dionis considered a ranula as an encysted tumour of the melliceris kind. Munick, better acquainted with the modern discoveries of anatomy, does not mistake the nature of the present disease; and he expressly says, that the affection originates from a thick saliva, which, not being able to pass out of the salivary ducts, accumulates under the tongue, so as to cause a swelling in that situation. Far from adopting the opinion of Munick, Heister fell back to that of Fabricius, and borrows every thing from this author. Lastly, De la Faye in his notes on Dionis, adopted Munick's sentiments: he says, "There are two sorts of ranulæ; some, which are round, and situated beneath the tongue, seem only to be produced by a dilatation of the excretory duct of the sublingual gland; the others are longer than they are round, are situated at the side of the tongue, and are formed by a dilatation of the excretory duct of the inferior maxillary gland. The fluid which fills such tumours is the saliva, which gradually accumulates in them, in consequence of its viscidity and the atony of the duct."

Persons who move their tongues a great deal, and those who sing, have been set down as very liable to the present complaint; but this opinion, I believe, rests on no good foundation. The fluid in the tumour is precisely like white of egg; but it is thicker after having remained a long while in the swelling; and it is occasionally of a calcareous, and even stony nature. Ranula does not proceed from an inspissation of the saliva, as De la Faye supposed, but from an obstruction of the duct or orifices of this tube. The collection often produces a tumour of very large size; but the swelling generally bursts when it has attained the dimensions of a walnut, and then leaves an ulcer which cannot be healed while the real cause of the disorder remains unknown.

Mr. B. Bell saw an ulcer of this kind, which was treated with the utmost care for several months: various detergent and corrosive applications were employed; and even a mercurial course; but all in vain At length, the true cause of the disease having been ascertained, a cure was accomplished in a few days by removing a piece of calcareous matter, which, by obstructing the ducts, had first caused the swelling, and then ulceration.

The opening, when made with a lancet, and not of sufficient size, frequently closes up again. In this case, the swelling reappears some time afterward. The ancients made the same remark; and hence, Paré preferred the actual cautery to the lancet. Dionis had also seen ranulæ recur, after they had been simply opened with a lancet; and he recommends, for the prevention of this inconvenience, the application of a mixture of honey of roses and sulphuric acid to the inside of the cyst, so as to destroy it. As Louis remarks, all authors seem to regret that the situation of the tumour should prevent the sac from being totally

dissected out. The success which Fabricius ab Aquapendente experienced, when he merely opened the tumour its whole length, did not free him from this prejudice; and Heister says he should prefer extirpation, if the nature of the adjacent parts, liable to be wounded, were not a formidable objection. But if this pretended cyst, this pouch, is nothing else than the gland itself, or its duct, dilated by the retention of the saliva, it should not be irritated. Whenever a sufficient opening is made, no relapse takes place. Munick particularly advises such an incision, and Rossius mentions the smallness of the opening among the defects of the treatment, and its being a cause of the disease returning. However, he also recommends destroying the sac; but specifies for the purpose only astringent, drying applications, which act in a less powerful manner.

In a ranula of moderate size, there is nothing like a cyst absolutely requiring extirpation. It is generally enough to lay the cavity open, and cut off the edges of the incision, when they will not otherwise unite. M. Louis always observed that the radical cure depended on a fistulous aperture, through which the saliva continued to flow; and that when this opening was situated behind the lower incisor teeth, a very annoying ejection of the saliva took place in certain motions of the tongue. The cure cannot be complete unless this inconvenience be obviated. For this purpose such an opening for the saliva must be made as will not close.

[The most successful method of fulfilling this indication is by passing a needleful of thread through the body of the tumour, and suffering it to remain there as a seton. This practice I have uniformly pursued with success, and at the same time evacuating the contents of the sac. This method results in a radical cure with as much certainty as the injection or seton in hydrocele, by obliterating the sac. Great care must be taken in introducing the seton not to wound the lingual artery, a branch of which often runs along the frenum. I knew one instance in which this accident was followed by a hemorrhage so alarming as to require the actual cautery for its suppression.—*Reese.*]

A ranula, when of long standing, is sometimes so large as absolutely to hinder a person from articulating. Le Clerc has recorded a case in which the root of the swelling extended under the tongue; the tumour filled the whole mouth; the prominence which it formed outwardly was as large as a duck's egg; and the disease in its progress had made the teeth of both jaws project outwards. At some parts of its surface, a fluctuation was perceptible; other places were exceedingly hard. The patient, who could scarcely breathe, demanded assistance; and a puncture was made in the softest part of the outside of the swelling. A thick yellowish fluid issued out of the ranula. The opening was enlarged with a knife, and about a pint of gritty inodorous matter was extracted. There was no hemorrhage from the cut; and no sooner had the contents of the swelling been let out, than the patient began to articulate, which he had not been able to do for a long while. The sides of the tumour being so prodigiously distended, Le Clerc thought proper to destroy the inside of the cavity with a tent, dipped in a mercurial solution. The cure was completed in a month, and the tongue gradually regained its original size, a part of which it had lost.

But, as M. Louis observes, fortunate as the termination of this case was, it must not be indiscriminately set down, that destroying the cyst or even opening the tumour, is always requisite. A more simple method will sometimes succeed. In a particular case, which this gentleman has related, a sinuosity, which divided the swelling into a right and left portion, made him suspect that it consisted of two sacs in contact with each other. On each side, in front, and in the same line, there was a point, which was the orifice of the salivary duct somewhat dilated, and blocked up with a viscid matter. Having very easily passed a small probe into the orifices, a matter similar to white of egg made its escape. A small leaden probe was passed into each opening, and two days afterward the sacs were emptied again, and two pieces of lead somewhat larger introduced. The patient was advised to take out the pieces of lead every morning, empty the swelling, and then replace them. In a fortnight, the openings having been kept continually dilated, had no tendency to close, the saliva did not accumulate, and the ranulæ never appeared again.

In certain cases, the above means are quite inadequate, and the tumour must be totally extirpated. Boinet related to the French Academy a case, in which the swelling not only filled the whole mouth, but one-half of the tumour projected out, and a cure could only be accomplished in the latter manner. The two upper incisor teeth on the left side were lodged in a depression observable there; and the canine tooth of the same side, forced outwards by the mass of the disease, had pierced the lip near its commissure. A fluid, resembling mucus, flowed from a narrow aperture at the lower part of the swelling. The tongue could not be seen, so much was it pushed backwards, and for some time the patient had only subsisted on liquid food, which he was first obliged to convey to the back of the throat with some mechanical contrivance. The four incisor teeth, two canine, and first grinders of the lower jaw, had been pushed out of their sockets, by the pressure of the swelling. The patient's aspect was alarming, and he was threatened with suffocation. Extirpation was deemed necessary, and it was performed with all due caution. The large cavity thus occasioned was filled with lint. The lower jaw being diseased, Boinet scraped some of its surface off, and covered the places with lint, either dry or dipped in spirit of wine. Some exfoliations followed, and the fungous granulations which grew were repressed with proper applications. In three months, the parts were healed in so regular a manner, that the motion of the tongue was not in the least obstructed, and no change continued, except the alteration of the voice, occasioned by the loss of teeth.—(See *Encyclopédie Méthodique, art. RECLINATION. A term employed in Germany, to denote the operation of turning a cataract, so as to change the position of its anterior and posterior surfaces.—(See *Cataract.*)

RECTUM. Many cases, in which this bowel is more or less concerned, are treated of in other parts in this Dictionary, and therefore it will only be necessary for me here to refer to them, and then notice some diseases of the same bowel, which are not considered in other articles. For an account of piles, hemorrhoidal excrescence, and other tumours of the rectum, see *Hemorrhoids*; and for that of prolapsus ani, fistula in ano, and imperforate anus, see *Anus.* Under the head of *Alvine Concretions,* I have noticed the dangerous obstruction of the rectum by masses of indurated matter. In the article *Lithotomy,* the mode of cutting through the rectum into the bladder, for the purpose of extracting a calculus from the latter organ, is explained; and if the reader refer to *Bladder,* he will there find a description of the method of tapping it from the rectum.

Scirrhus, or *stricture of the rectum,* sometimes called the *scirrho-contracted rectum,* and sometimes *cancer,* especially when the case is inveterate and in a state of ulceration, is a disease which has received much elucidation from the writings of Desault, Sir Everard Home, Dr. Sherwin, Mr. White, Mr. Copeland, Mr. Calvert, and Mr. Salmon. Most of the ordinary unmalignant strictures which have fallen under the care of Mr. Salmon were situated between five and six inches from the anus. Their next most frequent situation, he says, is at the junction of the sigmoid flexure of the colon with the rectum; "the very reverse of which happens in the true carcinomatous affection of the rectum, which will most commonly be found near the orifice; the disease in all probability originating in the mucous glands of the intestine, which are most prevalent towards the inferior part of the bowel."—(*Salmon, On Stricture of the Rectum,* p. 21.) In the various descriptions given of the complaint by these and other writers, one great point of difference is remarkable, viz. that some of them represent the case as always of an incurable nature, while others consider it as admitting of relief, at least when it has not made considerable progress, and the parts are free from ulceration. "Many strictures of the rec-

tum (as a judicious writer has remarked) are in their nature quite harmless, injurious only inasmuch as they present a mechanical obstruction, or disorder the functions of the alimentary canal, and fatal only from neglect. In many cases, also, great thickening and induration prevail, without the least tendency to cancer; at least, the latter disease has not supervened, even after an interval of many years."—(*On Hemorrhoids, Strictures, &c. of the Rectum*, p. 120.) According to Desault, scirrhus of the rectum is not uncommon at an advanced period of life, and the disease is said to afflict women more frequently than men, as, from a table kept at the Hôtel-Dieu, it appeared that ten cases out of eleven occurred in females; a proportion far exceeding what has been noticed in this country. Indeed, Mr. Calvert, speaking of strictures of the rectum generally, sets down their greater frequency in one sex than the other as doubtful, and scarcely worthy of notice.—(*Op. cit.* p. 122.) If it were not for the fact that Desault sometimes effected a cure of the disease in its early stage, I should venture to conclude, that his observations apply entirely to the true scirrhus or cancer of the rectum, which I believe rarely or never occurs in young patients, but, as Desault states, is not very unfrequent in elderly persons. My friend, Mr. Copeland, in his practical remarks, does not confine himself to really scirrhous and cancerous affections, but comprehends strictures of the rectum from a variety of causes; and this accounts for his statement, that the disease "*attacks people of almost all ages*, but is most common about the middle age." However, he agrees with Desault that women are more frequently affected than men. He admits that it is sometimes cancerous, though not so often as is generally imagined, the mere induration not being an unequivocal proof of it. When the disease is really cancer, it is usually attended with more severe pain, darting through the pelvis to the bladder and the groin. The countenance is of a sallow leaden cast.—(*On the principal Diseases of the Rectum and Anus*, p. 15—17.)

Sometimes the disease extends over a considerable length of the gut, but is generally more circumscribed. The coats of the bowel become much thicker and harder than natural. The muscular is subdivided by membranous septa, and the internal coat is sometimes formed into hard, irregular folds. The surface of the inner membrane is occasionally ulcerated, so as to form a cancerous disease. Every vestige of the natural structure is sometimes lost, and the gut is changed into a gristly substance. The cavity of the bowel is always rendered narrow at the scirrhous part, and is sometimes almost obliterated. When the passage through the gut is very much obstructed, the bowel is always a good deal enlarged just above the stoppage or stricture, from the accumulation of the fæces there. As the disease advances, adhesions form between the rectum and adjacent parts, and ulcerations produce communications between them.

Besides a spasmodic form of stricture of the rectum, a case, the real existence of which is perhaps questionable, Mr. Calvert notices the examples attended with change of structure. In some cases, he says, the contraction is chiefly owing to a thickened and indurated state of the mucous membrane, arising from inflammation, or some chronic alteration of texture; but that when the disease has existed a considerable time, the mucous, cellular, and muscular coats become more or less affected; so that, on dissection, it is often impossible to determine in which the disease originally commenced. He describes other cases, in which the cavity of the rectum is nearly obliterated by the presence of hard, painful tubercles. "This disease (he observes) bears some resemblance to the first stage of malignant stricture, at least as it appears in some cases; but it is evidently of quite a different nature, as it is easily cured by compression."—(*P.* 129.) Lastly, he adverts to carcinomatous strictures of the rectum which are deemed incurable. The disease is described by him as generally commencing at one side of the gut, just above the upper part of the internal sphincter, where a smooth, but hard and knotty projection may be felt. Mr. Salmon also represents carcinomatous disease of the rectum as being generally within reach of the finger.—(*On Stricture of the Rectum*, p. 62.) By degrees, the disease, which was probably confined at first to the glandular structure of the internal membrane, extends around the gut, changing the structure of the adjacent parts. However, Mr. Calvert explains, that carcinomatous stricture is not confined to the lower part of the rectum, but is often met with higher up, and especially in the sigmoid flexure of the colon. He remarks, that a considerable obliteration of the cavity of the rectum may proceed from an inflammation or ulceration, and subsequent adhesion of hemorrhoidal tumours, resembling, when the swellings are not of long standing, that form of stricture which arises from an infiltration of coagulable lymph in the relaxed folds of the mucous membrane of the bowel; but, in other instances, where such tumours are of older date and more solid, resembling the tubercular form of stricture.—(*P.* 138.)

Mr. Salmon describes the surface of the rectum as sometimes feeling indurated and irregularly thickened to a considerable extent. By degrees, the prominences ulcerate, and an absorption of the inner coat of the bowel is produced by the pressure of the growth of a new substance. He refers to two preparations of the scirrho-contracted rectum in a very advanced stage of the disease. In both, the mucous and the muscular coats of the bowel are absorbed, in consequence of the pressure of a new substance, which, in one instance, has made its way through the bladder; in the other, through the vagina.—(*Salmon on Stricture of the Rectum*, p. 63.)

As the disease at first is not very painful, it is usually not much noticed till somewhat advanced. There is perhaps no disease, as Mr. Calvert has noticed, in which the symptoms, arising from derangement of other parts, are so predominant over the local; and "there can be no doubt that in many cases of iliac passion, and obstinate constipation, arising from this source, death takes place without the slightest suspicion of the cause. In other cases, especially when the disease is of a malignant nature, it is not unfrequently confounded with scirrhus of the uterus."—(*P.* 123.) He also adverts to a case, in which a stricture of the rectum was lately mistaken for an intus-susception, by some practitioners "at the pinnacle of professional eminence." Mr. C. Bell, in one case where he attempted to puncture the bladder, and in another where he was about to divide a fistula in ano, felt his finger stopped by strictures of the rectum, of which the patients had no suspicion. The patient is at first habitually costive, or affected with what is called a torpid state of the bowels, and usually voids his stools with a little difficulty. In time, a good deal of pain is felt in the part affected, especially at stool, after which some relief is experienced. "As the gut continues to decrease in diameter (says Mr. Copeland), the efforts to expel the fæces become more violent, and the consequent progress of the disease more rapid. The stools, which have been long evacuated with difficulty, become contracted in size, appearing like earth-worms in their form, or small pellets;" and, if the finger be introduced into the rectum, "the gut will be found either obstructed with small tubercles, or intersected with membranous filaments; or else the introduction of the finger will be opposed by a hard ring of a cartilaginous feel, composed of the diseased inner membrane of the intestines." These states, as Mr. Copeland observes, are very different from the regular tumour, on the anterior part of the rectum, occasioned by an enlargement of the prostate gland; a case apt to be suspected. "As the disease advances (says the same author), the fæces become more fluid, and there is a thin sanious discharge from the anus, accompanied with tenesmus." Mr. Calvert notices, as the most characteristic symptoms, an unusual distention of the colon; the extension of pain, felt about the upper part of the sacrum, down to the feet, in the course of the large nervous trunks; the decrease of the tenesmus after a sufficient evacuation; and the scanty motions of irregular or figured appearances. The latter effect, however, he says, is not always present throughout the disease, for if the contraction be at the upper part of the rectum, the motion may be of the usual size and appearance.—(*P.* 147.) According to Desault, pus and blood may sometimes be noticed with the excrement, particularly when the disease has advanced to the ulcerated state. The carcinomatous stricture is said to be always attended with more or less of a burning sensation, or acute shooting pains at the seat of the disease, except at its very beginning. Sometimes, when a great part of the stricture has been destroyed by ulceration, the motions are voided without much

effort, but not without intense suffering.—(*Calvert, p.* 148—150.) The patient at length becomes sallow; frequent eructations of air from the bowels torment the patient, and render his life miserable; the constitution suffers, and dissolution follows. Severe tenesmus attends the whole course of the disease.—(*Œuvres Chir. par Bichat, t.* 2.)

Sometimes a small fistulous orifice at the verge of the anus communicates with the inferior portion of the diseased part. Such a fistula, in a case recorded by Sir Everard Home, was half an inch in length.—(*Obs. on Cancer, p.* 133.)

Desault often saw the disease form a communication between the rectum and vagina, and the feces passed through the latter part. In the latter stage of the affliction, the rectum, bladder, vagina, uterus, and adjacent parts, are all involved in one common ulceration. And, according to Mr. Calvert, the surface of the os sacrum, or even that of the lumbar vertebræ, may become involved in the extent of the disease, the rectum being sometimes so firmly connected with the former bone as to be very difficultly separable from it even with a knife.—(*P.* 137.)

When the disease has attained the ulcerated state, it is probably always incurable. Palliatives can only now be resorted to, such as anodyne and emollient clysters, the warm-bath, &c., with the exhibition of medicines like opium, cicuta, uva ursi, &c. Claudinus applied his remedies to the inside of the bowel, by means of tents, and did not employ the latter as a mode of curing the disease when less advanced. Valsalva introduced a cannula, pierced with numerous holes, and then made his patient get into a bath, so as to let the fluid enter the intestine. Numerous practitioners, among whom is Morgagni, made mercurials the base of their treatment, from a supposition that the complaint was of venereal origin. I believe the latter opinion is, at present, entirely abandoned by all the most judicious surgeons in England, and this, whether mercury ever prove useful or not.

When the disease is not attended with ulceration, the contraction and thickening of the gut may be diminished by introducing bougies, keeping them for a certain time, every day, so introduced, and increasing their size gradually. The pressure of these instruments seems to lessen the disease, and stop its progress; a proof, at all events, that the nature of one form of scirrho-contracted rectum differs from that of a common malignant scirrhus. Desault used to employ long tents, made of lint, smeared with cerate, and passed into the bowel by means of a probe, with a forked end. Their size was gradually increased, so as to keep up the compression, to which it was conceived all the good was owing. Their length was also augmented by degrees. At first, fresh ones were introduced twice a day. When any hardnesses were situated on the outside of the anus, Desault cured them on the same principle, viz. by making pressure on them with compresses and a bandage. In this manner, he effected the cure of a scirrho-contracted rectum. The patient was taught to pass occasionally the tents, without assistance, in order to prevent a relapse.

Instead of tents, modern surgeons employ bougies for the dilatation of strictures in the rectum. When from habitual costiveness, the altered figure of the stools, and other circumstances, there is reason to suspect organic obstruction to the passage of the feces, and this suspicion is confirmed by an examination of the rectum with the finger, "the first object of the surgeon (says Mr. Copeland) should be an enlargement of the obstructed part, by the introduction of a bougie. This should be of such a size, as to pass, when well lubricated with oil, without much difficulty or pain. Sometimes, when the disease has been of long continuance, it will be necessary to begin even with a large-sized urethra bougie, or one of the same size as those which are made for a stricture of the œsophagus, and of a length that is likely to pass beyond the end of the stricture, that is, about six, or seven, or eight inches. But I think it of consequence to use a bougie at first, which is rather too small, than too large."—(*P.* 29.) When it has remained for half an hour, or more, it is to be removed, and passed again the next day, the same-sized bougie being continued for several days. In the introduction of the bougie, Mr. Copeland cautions the practitioner not to mistake the projection of the sacrum for a stricture of the gut; a mistake which, he says, has often been made, and as I believe, too often wilfully, and from motives of imposition. Pressure on the rectum by the retroverted uterus (*C. Bell*), an enlarged ovarium, or other tumour, may also lead an inattentive surgeon to mistake the case for a stricture. Mr. Calvert has seen the bougie employed a long while in one example, where the real disorder arose from a biliary concretion imbedded in the parietes of the rectum.—(*On Hemorrhoids, and other Diseases of the Rectum, p.* 167.) This gentleman conceives, that an ivory ball, affixed to the end of a silver wire, is a good instrument for ascertaining the exact situation and extent of strictures of the rectum.—(*P.* 169.) When the stricture is just above the sphincter, some information of the state of the parts, he says, may be gained by employing the speculum ani, but he adds, that whenever there is organic stricture near the anus, this instrument should be used with caution, as any sudden distention of the parts is always very injurious.—(*P.* 170.) Mr. Copeland advises the bowels to be kept constantly lax, by the use of castor oil, or electuary of senna, during the whole of the treatment.—(*P.* 30.) Whatever be the nature of the stricture, whether it be that kind in which the rectum is obstructed by tubercles, by membranous filaments intersecting its canal (which two species, Mr. Copeland says, are the most easily relieved), or whether it be the indurated stricture, from the thickening of the coats of the intestine, this local treatment is equally necessary. The plan is to be persisted in until a full-sized bougie will readily pass, and even after all symptoms have disappeared, it is recommended to introduce the bougie, and withdraw it again, once every two or three days, for some time, in order to prevent a relapse. The indurated, annular stricture, which long resists the bougie, Mr. Copeland sometimes divides with a probe-pointed curved bistoury on the side which is contiguous to the os sacrum; and he has frequently seen the late Mr. Ford perform the same operation.—(*P.* 34.) This practice, which originated with Wiseman, has also been practised by others with success.—(See *Dr. Jamieson's Case, in American Recorder, April*, 1822.) When the disease is either combined with venereal symptoms, or there is any reason for suspecting it to be itself "the solitary symptom" of lues, Mr. Copeland joins Desault in recommending a trial of the effect of mercury, in conjunction with bougies.—(*P.* 44.) The formation of abscesses, he remarks, is very frequent in the advanced stages of the disease, and he has often seen the common operation for fistula done under such circumstances without success.—(*P.* 35.)

The use of castor oil and electuary of senna, and throwing into the rectum a pint of thin water-gruel and a dessert-spoonful of castor oil, with the common elastic bottle and pipe, are also recommended by Mr. Salmon. It is only when the bowels are very inert, and the lower part of the belly hard and full, that he has recourse to aperient draughts of rhubarb, sulphate of potassa, and senna.

Besides tents and bougies, which latter Mr. Calvert thinks may be sometimes usefully made the vehicle of local applications, or be what is called medicated, this gentleman enumerates among the plans of dilating the stricture a prepared gut, introduced beyond the stricture, and then distended with water; in other words, Mr. Arnot's dilator. This method, he says, may be adopted where the bougie causes great irritation.—(*P.* 173.)

When a stoppage of urine occurs in the advanced stage of the disease, Mr. Copeland advises surgeons not to use the catheter hastily.—(*P.* 39.) And in the event of great pain and irritation in the rectum, he has seen the greatest benefit derived from the local application of opium, either in a clyster, or by the introduction of one or two grains of the medicine within the anus. He also speaks favourably of the effects of the warm bath and fomentations, in giving temporary relief; and he has also exhibited in these cases the pil. extracti conii cum hydrarg. submur. with considerable advantage.

When stricture of the rectum is of a cancerous nature, Mr. Calvert sets down every known remedy as inadequate to arrest its progress. A mitigation of sufferings is all that can be aimed at. "Diluent injections, combined with opium, conium, or similar remedies, may afford a temporary relief in the ulcerative stage;"

but, says this writer, "the greatest advantage is derived from carefully introducing a hollow tube of elastic gum, through which the feces are drawn off by injecting tepid water." Dilating the passage with any other view than that of maintaining an outlet for the feces, he considers quite useless. "A soft tent, composed of lint, smeared with some mild fresh ointment, will in general answer this purpose. If there be much pain and inflammation, fomentations may be used; and leeches applied in the vicinity of the anus or over the sacrum. The bowels should be kept moderately open with castor oil, or some other mild laxative, which, if it is thought necessary, may be combined with the extract of hyoscyamus, cicuta, or opium; but the latter is in general less admissible, because it is more liable to counteract the effect of the laxative, and produce a torpid state of the bowels."—(*P.* 187.)

According to Mr. Salmon, in true carcinoma of the rectum, the use of bougies dangerously aggravates the disease. The only palliative means recommended by him are, leeches to the anus, the introduction of a grain or two of opium into the rectum, and perseverance, night and morning, in injections containing from forty to sixty drops of laudanum. He particularly cautions the surgeon not to introduce the clyster-pipe more than an inch, or an inch and a half, within the sphincter, lest too much irritation of the parts be excited.—(*P.* 65.) This gentleman differs from most writers on the subject, in advising the bougie to be passed at intervals of from three to five days, instead of daily. His bougies (which are eleven inches long) are composed of fine linen, very heavily coated with wax and diachylon plaster, mixed with a small quantity of lampblack. They are to be softened in very hot water, just before they are employed.—(See *Salmon on Strictures of the Rectum*, *p.* 49.) When the stricture is attended with great local irritation, he smears the bougie with a salve composed of one ounce of elder ointment, and a scruple of very finely powdered opium; and when the stricture is suspected to be connected with syphilis (a doctrine, however, he in another place renounces), he smears the bougie with mercurial ointment.—(*P.* 51.)

A fatal case of mortification of the rectum is detailed by Larrey. *Parisian Chirurgical Journal*, *vol.* 2. *p*, 398, *&c.* See *J. L. RESOLUTION. The subsidence of inflammation without abscess, ulceration, mortification, &c. Also the dispersion of swellings, indurations, &c.

RETENTION OF URINE. See *Urine, Retention of.*

RETROVERSIO UTERI. A turning backward of the womb. See *Uterus, Retroversion of.*

RICKETS. (*Rachitis.*) Is mostly met with in young children; seldom in adults. Morand, however, (*Acad. des Sciences*, 1753), mentions an instance, in which an adult became affected. The disease, it is said, may even take place in the fœtus in utero; but the most common period of its commencement is in children, between the ages of seven or eight months and two years. Hence, as Mr. Wilson observes, its origin has frequently been imputed to the effects of dentition. He adds, that he has often known it make its appearance after this time, and that it not unfrequently attacks the spine a little while before puberty, and may do so even later.—(*On the Structure and Physiology of the Skeleton, &c. p.* 162.) Pinel has given a description of the skeleton of a rickety fœtus.—(*Fourcroy's Journal.*) The disease seems to consist of a want of due firmness in the bones, in consequence of a deficiency in the phosphate of lime in their structure. The causes of the affection are involved in great obscurity. Authors have referred them to scrofula, scurvy, lues venerea, difficult dentition, &c.; and Richerand still firmly believes, that rachitis is only one of the effects of scrofula in its worst forms.—(*Nosographie Chir. t.* 3, *p.* 148, *edit.* 4.) But these are merely conjectures, which will not bear a rigorous investigation. Boyer, in particular, has well exposed their invalidity.—(*Traité des Mal. Chir. t.* 3, *p.* 611.)

Rickety subjects are often at the same time scrofulous; and this is, probably, the only reason for scrofula being accounted a cause of the other affection. The particular appearances of rickety children we need not detail, as every one is familiarly acquainted with them: such children are usually of a bad, weak constitution, and their limbs and bones become bent in directions determined by the action of the muscles, and the weight and pressure which they have to sustain. When the affection is very general, the spine becomes shorter, and is curved in various directions; the breast becomes deformed, not only in consequence of the curvature of the spine, but by the depression of the ribs, and projection of the sternum. The bones of the pelvis fall inwards, and the os pubis generally approaches the sacrum. The latter circumstance is one of the causes of difficult parturition. The clavicles become more bent and prominent forwards; the os humeri is distorted outwards; the lower ends of the radius and ulna are twisted in the same direction; the thighs are curved forwards or outwards; the knees fall inwards; the spine and front surface of the tibia become convex; and the feet are thrown outwards.

According to Mr. Stanley, when the tibia and fibula become curved, they sometimes "acquire increased breadth in the direction of the curve, losing a proportionate degree of thickness in the opposite direction. Hence the bones become, as it were, newly modelled, passing from the cylindrical into the flattened form. This would seem to be designed for the purpose of enabling them to support more efficiently the weight of the body, since by this alteration they acquire increased breadth and power of resistance in that direction where the greatest strength is required. I have never noticed (says Mr. Stanley) any expansion in the articular ends of rickety bones, as is mentioned by some authors. I should therefore feel inclined to believe that there has existed only the appearance of such a phenomenon, the ends of the bones having appeared swollen, in consequence of the emaciation of the surrounding soft parts.—(See *Med. Chir. Trans. vol.* 7, *p.* 402—405.)

When the thoracic viscera are considerably oppressed by the alteration in the figure of the chest, produced by rickets, the disease may bring on fatal consequences.

Boyer has thus described the appearances of rickety bones:—They are lighter than natural, and of a red or brown colour. They are penetrated by many enlarged blood-vessels, being porous, and, as it were, spongy, soft, and compressible. They are moistened by a kind of sanies, which may be pressed out of their texture, as out of a sponge, or rather a macerated hide after it has been tanned. The walls of the medullary cylinder of the great bones of the extremities are very thin, while the bones of the skull are considerably increased in thickness, and become spongy and reticular. All the affected bones, especially the long ones, acquire a remarkable suppleness; but if they are bent beyond a certain point, they break, &c. Instead of being filled with medulla, the medullary cavity of the long bones contains only a reddish serum, totally devoid of the fat, oily nature of the other secretion in the natural state.—(See *Boyer, Traité des Maladies Chir. t.* 3, *p* 619.) The consistence of several rickety bones, examined by Mr. Stanley, was nearly that of common cartilage. They presented throughout an areolated texture, and the cells were in some parts large, and contained a brownish gelatinous substance. This gentleman did not find the periosteum thickened, as Bichat has described it.—(*Anatomie Générale, t.* 3.) The investigations of Mr. Stanley have also discovered, that in the process by which rickety bones acquire strength and solidity, there is always an undeviating regularity in the situation, extent, and direction of the deposited earthy matter. "Thus it is obvious (says this gentleman) that, in the curved bone, the part where there is the greatest need of strength to prevent its farther

yielding, is in the middle of its concavity, or in other words, in the line of its interior curve; and it is just in this situation, that strength and compactness will be first imparted to the bone by the deposition of phosphate of lime. It will be farther found, that the greatest resistance being wanted at this part, the walls are accordingly rendered thicker here than elsewhere, and the degree to which this excess in thickness is carried, bears an exact ratio to the degree of curvature which the bone has undergone."

Mr. Stanley's observations also prove, that the bony fibres are arranged obliquely across the axis of the bone, in a direction calculated to augment its strength. Lastly, we learn from the same authority, that if a long bone, like the tibia, be very much bent, while it has to support a great superincumbent weight, the deposition of the bony matter may not be confined to the thickening of the walls of the concave side, but may extend across the medullary cavity, rendering the bone here perfectly solid, and thereby greatly strengthened. —(See *Obs. on the Condition of the Bones in Rickets, &c. by E. Stanley, in Medico-Chir. Trans. vol.* 7, *p.* 404, *et seq.*)

We learn from the late Mr. Wilson, that, for many years, he had also exhibited in his lectures preparations illustrating the fact of the abundant deposition of osseous matter, "when the bones begin to recover from the disease, at the part where it is most wanted, viz. on the inner part of the concave surface of their curve." —(*On the Skeleton, &c. p.* 167.)

Many very rickety and deformed infants improve as they grow up, and acquire strength. The deformity of their limbs spontaneously diminishes, and the bones gain a proper degree of firmness, a due quantity of the phosphate of lime being deposited in their texture.

It is a question, whether the restoration of the proper figure of the bones can be promoted by the constant pressure of bandages, and mechanical contrivances sold in the shops. Some authors contend, that in very young children, machines are useless, as the confinement and inactivity of the muscles, necessarily occasioned by such contrivances, must increase the general debility, and consequently the disease.

Notwithstanding the praises which have been bestowed on those mechanical means by their inventors, and even by respectable authors, says Boyer, they are not now used by any enlightened, judicious practitioners, it being generally agreed that it is best to leave to nature alone, aided by good medical treatment, the duty of rectifying bones deformed by the rickets.—(*Traité des Mal. Chir. t.* 3, *p.* 627.) Delpech expresses himself still more strongly against the employment of machinery.—(See *Précis Elémentaire des Maladies Chir. t.* 3, *p.* 740, &c.) However, these opinions against mechanicle contrivances for the improvement of rickety bones are not meant to apply to machines for rectifying distortions of the foot. In such cases, the malformation does not depend on constitutional causes, and mechanical means will do whatever is possible.

No medicine is known that possesses any direct efficacy in rickets.—Tonics are indicated, and should be employed. Bark, especially the sulphate of quinine, may be tried, as well as steel medicines: to iron filings a great deal of efficacy has been ascribed.—(See *Med. Comment. vol.* 2, *p.* 48.) In particular, the functions of the bowels should be duly regulated by medicine. The disease appearing to consist in a deficiency of lime in the bones, proposals have been made to exhibit internally the phosphate of lime; but this chemical project has had no success.—(See *Bonhomme's Memoir on Rachitis, in Duncan's Annals for* 1797.)

Several circumstances, considered by Mr. Wilson, tend to prove, that this scheme could present no chance of benefit, because there is no proof of a deficiency of lime in the system, though the arteries of the bones do not deposite it in the natural degree.—(See *Wilson on the Skeleton, &c. p.* 163, *&c.*)

More good is generally effected by keeping children in healthy situations, and in a salubrious air, than by any medicines whatever. Light, wholesome, nutritious, easily-digestible food; cold bathing; good nursing; regular gentle exercise; or airings in a carriage; the use of the flesh-brush, &c. are also highly serviceable. The constitutional treatment of rickets belongs more properly to the physician than the surgeon; and it is not necessary to introduce more of the subject into a Dictionary expressly allotted to surgery.—(See *Mollities Ossium.*) Consult *Buchner de Rachitide, Argent.* 1754. *Glisson de Rachitide, sive Morbo Puerili, Ludg. S

SABINA. Savine. The use of the leaves of this plant, in forming the active ingredient in the ointment commonly preferred for keeping open blisters, has been explained in the article *Blisters.* The other chief surgical use of savine is as a stimulating application for destroying warts, and other excrescences. For the latter purpose, it is generally powdered, and mixed with an equal proportion of subacetate of copper. The same powder is also sometimes employed by surgeons for maintaining the hollows in which peas are inserted in issues. The best plan is, first to wet the peas, then roll them in the powder and put them in this state on the issue. But when the whole surface of the issue has risen high above the level of the skin, the powder must be sprinkled all over the sore, so as to produce an absorption of the high granulations. Indeed, even in this manner, a good cavity often cannot be obtained; and it becomes necessary to destroy the surface of the issue, by rubbing it with caustic potassa or potassa cum calce.

SAL-AMMONIAC. *Ammonia Muriata. Muriate of Ammonia.* Employed a good deal by surgeons, as an ingredient in discutient lotions.—(See *Lotio Ammon. Mur.*)

SALIVARY FISTULÆ. See *Parotid Duct.*

SANIES. (*Latin.*) A thin, serous, fetid matter, discharged from fistulæ, unhealthy sores, &c. It is sometimes tinged with blood.

SAPO TEREBINTHINÆ. (*Starkey's Soap.*) ℞. Potassæ subcarbonis calidi ʒ j. Olei terebinth. ʒ iij.—The turpentine is gradually blended with the hot subcarbonate of potassa in a heated mortar. Indolent swellings were formerly rubbed with this application, and, perhaps, some chronic affections of the joints might still be benefited by it.

SARCOCE'LE. (From σὰρξ, flesh; and κήλη, a tumour.) A fleshy enlargement of the testicle.—(See *Testicle, Diseases of.*)

SARCO'MA, or *Sarcósis.* (From σὰρξ, flesh.) A fleshy tumour.—(See *Tumours, Sarcomatous.*)

SARSAPARI'LLA. The root of sarsaparilla was brought into Europe about 1530. It was at first reputed to possess singular efficacy in venereal cases; but afterward lost all its fame. It was again brought into notice by Dr. W. Hunter, who advised Dr. Chapman to make trial of it in a bad case of phagedenic bubo; and the benefit obtained in this instance led Dr. Hunter to extend the recommendation of the medicine Sir W. Fordyce stated that sarsaparilla would quickly relieve venereal headaches and nocturnal pains, and,

if persisted in, cure them; that in emaciated or consumptive habits from venereal cause, it was the greatest restorer of appetite, flesh, colour, and strength which he knew of; that when mercurial frictions had been previously employed, it would generally complete the cure of the disease of the throat, nose, palate, or spongy bones; and that it would promote the cure of blotches and ulcers, and sometimes accomplish it, *even without mercury*; though in this circumstance there was danger of a relapse. Sir W. Fordyce pronounced sarsaparilla to be of little use in chancres; but that, when these or buboes could not be healed by mercury, it would often cure, and always do good. He allows, however, that in all venereal cases *sarsaparilla is not to be trusted, unless preceded by, or combined with, the use of mercury;* and he thought sarsaparilla would, probably, always cure what resisted mercury.—(*Medical Obs. and Inq. vol.* 1.)

Cullen considered sarsaparilla as possessing no virtues of any kind; for, says he, "tried in every shape, I have never found it an effectual medicine in syphilis, or any other disease."—(*Mat. Med. vol.* 2.)

Mr. Bromfield declares, that he never saw a single instance in which sarsaparilla cured the venereal disease without the aid of mercury, either given before or in conjunction with it.—(*Pract. Obs. on the Use of Corrosive Sublimate, &c., p.* 78.) Mr. Pearson also contends, that sarsaparilla *has not the power of curing any one form of the lues venerea;* but he allows that it may suspend for a time the ravages of that contagion, the disease returning, if no mercury should have been used. This gentleman admits also, that sarsaparilla will alleviate symptoms derived from the venereal virus. He maintains, that the exhibition of sarsaparilla does not diminish the necessity for giving less mercury. Nocturnal pains in the limbs, painful enlargements of the elbow and knee, membranous nodes, cutaneous ulcerations, and certain other symptoms resembling venereal ones, are often experienced after a full course of mercury. Such complaints, Mr. Pearson allows, are greatly benefited by sarsaparilla and exasperated by mercury; and he observes, that it is from these complaints having been mistaken for venereal ones, that the idea has arisen that sarsaparilla has cured syphilis when mercury had failed. Mercury and the venereal poison may jointly produce in certain constitutions symptoms which are not strictly venereal, and are sometimes more dreadful than the simple effects of syphilis. Some of the worst of these appearances are capable of being cured by sarsaparilla, while the venereal virus still remains in the system. When this latter disease has been eradicated by mercury, sarsaparilla will also cure the sequelæ of a course of the other medicine.—(*Pearson on the Effects of various Articles in the Cure of Lues Venerea*, 1807.)

The value of many of the foregoing opinions is much affected by the results of modern inquiries into the nature of the venereal disease, the possibility of generally curing which, without the aid of mercury, seems well established, though the expediency of the method is another question.

SCA'LPEL. (From *scalpo*, to scrape.) Originally a raspatory, or instrument for scraping diseased bones, &c. The term now generally signifies a common, straight, surgical knife.

SCA'RIFICATION. (From *scarifico*, to scarify.) The operation of making little cuts or punctures in a part for the purpose of taking away blood, letting out fluid in anasarcous cases, or the air of emphysema.

SCIRRHUS; SCIRRHOMA; SCIRRHOSIS. (From σκιρρόω, to harden.) The etymological import of these terms seems merely to be any induration. The first is now generally restricted to the induration, which precedes cancer in the ulcerated state.

SCLERIASIS; SCLEROSIS. (From σκληρόω, to harden.) A hard tumour or induration.

SCRO'FULA, or SCROPHULA. (From *scrofa*, a sow.) So named, as is commonly supposed, because swine are said to be subject to it, though the correctness of this etymology is rendered very questionable by the remarks of Dr. Henning; and the statement that pigs are really liable to scrofula, would appear to be erroneous.—(See *Critical Inquiry into the Pathology of Scrofula, &c., p.* 1, 9.) Called also *struma*, and the *king's evil*, from the custom of submitting patients formerly to the supposed beneficial effects of the royal touch. A disease, one of the chief or most palpable symptoms of which is a chronic swelling of the absorbent glands in various parts of the body, which glands generally tend very slowly to imperfect suppuration. Our notions of scrofula, however, would be very imperfect were we to define the disorder to be a morbid state of the lymphatic glandular system. The first appearances, indeed, frequently consist of spots on different parts of the body, and of eruptions and ulcerations behind the ears. As a judicious author remarks, the system of absorbent glands, it is true, seldom or never fails to become affected in the progress of the disease; but there is reason to believe, that scrofula frequently appears for the first time in parts which are not of a glandular nature. There are, perhaps, but few, if any, of the textures of the human body, or of the organs which these textures form, that are not liable to attacks of scrofula, and to scrofula as an original idiopathic affection.—(*Thomson on Inflammation, p.* 134.) These sentiments are entirely at variance with those of Alibert, and many other moderns, who describe the disease as having its commencement in the conglobate glands, especially those of the neck (*Nosol. Naturelle, t.* 1, *p.* 441, *4to. Paris*, 1817); and they are equally opposite to the doctrine of Dr. Henning, who argues that the superficial absorbent glands alone are susceptible of the original action of the cause of this disease, and that if other parts become affected by it, such affection is consequential.—(*On the Pathology of Scrofula, chap.* 6.)

Scrofula generally shows itself during infancy, between the age of three and seven; sometimes rather sooner; but frequently as late as puberty, and in some instances, though a very few, not till a much more advanced period of life. In the latter cases, the disease is said to be rarely so complete or well marked as it is in young subjects. Sir A. Cooper mentions the period of growth generally, as the time of life for scrofula; and its commencement afterward, he agrees with most writers in pronouncing very uncommon. "Cette maladie (says Alibert) est communément le partage de la première enfance. Il est rare qu'elle se développe chez les adultes. Je l'ai pourtant observée chez des septuagénaires; mais presque toujours ce sont les effets de la dentition, qui la font éclore, et ceux de la puberté, qui la font évanouir."—(*Nosol. Naturelle, p.* 448.)

By some authors it is stated, that the disease seldom attacks the glands in children under two years of age. Dr. Thomson, however, has seen the glands affected before this period, and Dr. Cullen used to mention a case, in which the disease broke out in an infant only three months old; which is uncommon. But though glandular scrofula occurs most frequently in children, it is by no means confined to that period of life. Dr. Thomson has even found the lacteal glands affected with scrofulous inflammation in persons of very advanced age.—(*Lectures on Inflammation, p.* 136.) Probably, however, such patients had laboured under scrofulous complaints in their earlier days; and it merits notice, that some authors, like Dr. Henning (*p.* 110), do not regard enlargements of the mesenteric glands as an unequivocal specimen of scrofula. It is observed by Mr. Lloyd, that the susceptibility of different parts to the disease "is altered by age: thus, in children the upper lip, eyes, glands of the neck, and those of the mesentery are generally the parts first affected; the lungs, bones, and other parts being subsequently attacked. It happens sometimes too in children, that small lumps form under the skin in various parts of the body, which suppurate, ulcerate, and pursue the same course with scrofulous abscesses in general."—(*On Scrofula, p.* 5.) A species of warts, he says, also often forms about the face and neck of children of a scrofulous habit, but seldom in adults. "In more advanced age, the eyes, upper lip, and lymphatic glands are comparatively seldom affected; while the lungs, the other viscera, and the spongy parts of the bones are frequently attacked."

Scrofula is also as hereditary as any disease can be; that is to say, it is so as far as any particular kind of temperament or constitution can descend, more or less completely, from parents to children. Mr. White, Dr. Henning, and others have strongly censured calling the disease hereditary; but their observations only lead to these conclusions, that children born of scrofulous parents are not invariably affected with scrofulous diseases; and that sometimes one child has some strumous affection, while the parents and all the rest of the

family have no appearance of scrofulous habits. However, I still conceive, that neither Mr. White nor any other writer will maintain the opinion that scrofula does not much more frequently afflict the children of scrofulous parents, than the offspring of persons who have always been perfectly free from every tendency to any form of this affliction. Too numerous are the facts which occur to my own mind to allow me to entertain the smallest doubt that scrofula prevails in certain families. In this sense, I think the term *hereditary* perfectly accurate and allowable. But, at the same time, I beg the reader to understand, that I have no intention of questioning what seem to be irrefragable truths, viz. that the children of scrofulous parents often continue as long as they live entirely free from the disease; and that one child is sometimes afflicted, while its father, mother, brothers, sisters, and all the rest of its relations have never had any tendency to strumous disorders. It should also be recollected, that the doctrine of a congenital tendency to the disease in particular families is one which interferes with some theories which have been offered about the predisposing cause of the disease, as for instance with that of Dr. Henning, who declares that such cause is foreign to the body, and depends upon peculiarities of climate (*On the Pathology of Scrofula, p.* 69, *&c.*); an opinion which is incorrect only in respect to its exclusion of the influence of other circumstances. Two curious specimens of tuberculated lungs in the fœtus are preserved in Mr. Langstaff's museum, and have been adduced by Mr. Lloyd as positive proofs of scrofula being hereditary (*On Scrofula, p.* 23): however, I am not certain that they will be admitted as such by all parties, as tubercles of the lungs are not constantly regarded as a scrofulous disease. Yet the facts and arguments on this point, I think, are decidedly in favour of the doctrine; and Dr. Alison, who has treated very ably of the pathology of scrofula, has remarked, that "in most cases in which scrofulous diseases are fatal, the diseased action is in internal parts, and the first symptoms are obscure and equivocal. The chief and certainly the most characteristic appearances on dissection are tubercles in different stages of their progress."—(See *Edinb. Med. Chir. Trans. vol.* 1, *p.* 403.) The same writer every where treats of phthisis as decidedly a scrofulous disease.

When scrofula does not actually take place at a very early period of life, it is generally stated by writers, that the particular constitutions in which there is a disposition to the disease are, in a certain degree, distinguishable. In the individuals possessing the disposition in question, a peculiar softness and flaccidity of fibre are remarkable; their hair is more frequently light-coloured than dark; and their eyes are said to be more often of a blue than any other colour. The eyelashes are frequently long, and the pupils large. Their skin is generally very fine, and even handsome, both in regard to its outward texture and complexion. When pinched, it feels (as Sir A. Cooper observes) thinner than that of a healthy child, and the vessels may often be seen meandering under it. Subjects with scrofulous constitutions frequently have a thickening of the upper lip; this swelling is sometimes very considerable, and occasionally extends as far as within the nostrils. The extremities of the fingers are broad and flat, or *clubbed*, as the phrase is, just like what is seen in phthisical persons. Scrofula is also very often complicated with rachitis, or follows the latter affection; but there is as little reason for supposing rickets to arise from scrofula, as this latter from rickets. In some instances, however, the complexion is dark, and the skin coarse; but in these subjects, at least when young, the face is generally tumid, and the look unhealthy.—(*Burns on Inflammation, vol.* 2, *p.* 232.)

In many instances, the last joints of the fingers have been observed to be enlarged, and the belly is generally larger than usual.—(*Thomson, p.* 134.)

Mr. White denies that gray or blue eyes, light hair, and a fair complexion, ought to be considered as marks of a scrofulous disposition; for the majority of children in this country have light hair and eyes while young, which become darker as they advance in life. Now, as the majority of scrofulous patients are children and young subjects, and as most children in this country have naturally the kind of hair and eyes above described, Mr. White considers it inaccurate to lay any stress on persons affected with struma, or predisposed to this disease, having such appearances.—(*On the Struma or Scrofula, p.* 38, *ed.* 3.) However, it is to be recollected, that the greater frequency of scrofula in fair people is noticed in France, where the eyes are mostly dark. Thus Alibert, in his description of a patient disposed to the disease, takes notice of his swelled nostrils and upper lip; his florid complexion; his fair, delicate, and glossy skin; his cheeks of a lively-red colour; circumscribed, however, by a pallid bloatedness of the rest of the face; his blue eyes; dilated pupils; light hair; short neck; large head and lower jaw; flabby flesh; large, protuberant belly; strong intellectual powers, &c.—(*Nosol. Naturelle, p.* 442; also *Dict. des Sciences Méd. t.* 50, *p.* 281.)

Dr. Thomson expressly declares, that some of the worst cases of scrofula which he has seen, occurred in persons whose complexion and hair were of a very dark colour.—(*Lectures, p.* 134.) And every man of experience must be aware of one remarkable fact, namely, that many negroes are afflicted in this country with scrofula in its worst forms. Does not this fact indicate, at the same time, that it is climate which is most powerfully concerned in the production of the disease? since the African black, in his own country is nearly exempt from scrofula. After all, however, as the disease is undoubtedly very frequent in persons of fair skin, light eyes, &c. the term *alike*, at least in the sense of *equally*, may not be altogether correct in the following inference, viz. "that persons of every variety of complexion are *alike* subject to this disease, and that it is only necessary to place them in circumstances favourable to its developement to have it fully formed."—(*Lloyd on Scrofula, p.* 7.) The truth I believe is, that though children of dark hair and complexion are often attacked by scrofula, those of light hair and fair complexion are still more frequently afflicted, and this even in France, where the fact cannot possibly be referred to the number of fair children exceeding that of such as naturally have dark hair and complexion.

I believe the fact is now almost generally admitted, that females are rather more subject than males to scrofulous disease.—(See *Alibert, Nosol. Naturelle, p.* 449.)

According to Mr. White, struma prevails more extensively in temperate latitudes than in very hot or very cold climates. It is also more frequent in some parts of Europe than others; and in this country, it has been found to be most prevalent in the counties of Suffolk and Lancashire. At all periods, it seems to have been a very common complaint in this island. From history we learn that it was denominated the king's evil in the time of Edward the Confessor, who is supposed to have been the first that attempted to cure it by the royal touch. From a register kept in the royal chapel, we find that Charles II. touched 92,107 persons in a certain number of years; and this equally bigoted and useless practice was not discontinued till a recent period, when kings were found to be, as well as their poorest subjects, totally destitute of all supernatural power.

Scrofula is not communicable from one person to another; neither can it be conveyed into the system by inoculation. The opinion also, that scrofulous nurses may infect children, seems quite destitute of foundation.—(See *White, p.* 26, *&c.*)

Pinel and Alibert have purposely kept scrofulous and healthy children together in the same ward, without any of the latter receiving the complaint. Hébréard could not communicate the disease to dogs by inoculation. And G. T. Kortum, whose valuable work contains every thing known about scrofula at the period when it was written, tried in vain to impart the distemper to a child, by rubbing its neck every day with the pus discharged from scrofulous ulcers. Lepelletier, desirous of ascertaining the correctness of such experiments, has of late repeated them: he has made guinea-pigs swallow scrofulous matter; and he has injected it into the veins, and applied it to wounds; but in no instance was there even a temporary appearance of the disease being communicated. The same author also mixed scrofulous with vaccine matter, and inoculated with it; yet he never found the vaccine vesicle, thus produced, deviate in the least from its regular course. Lastly, Lepelletier inoculated himself with pus discharged from scrofulous sores, as well as with the serum collected under the cuticle of

a strumous patient after the application of a blister; but he remained free from every scrofulous ailment.—(See *Dict. des Sciences Méd. t.* 50, *p.* 294.) Our countryman, Mr. Goodlad, inoculated himself several times with the discharge from scrofulous sores and abscesses, and the result was, that the disease could not be thus transmitted.—(*On the Diseases of the Vessels and Glands of the Absorbent System*, *p.* 113.)

The parts which are most frequently affected by scrofula, next to the lymphatic glands, and perhaps the skin, are the spongy heads of the bones and the joints. The form which the disease assumes in the latter parts is particularly described in the article *Joints*. The disorder of the spine, attended with a paralytic affection of the lower extremities, is, no doubt, very frequently of scrofulous origin.—(See *Vertebræ*.) Spina bifida is a congenital disease, most frequently seen in children, whose parents are scrofulous.—(*Thomson's Lectures*, *p.* 133.) The abscess which forms in the cellular substance, between the peritoneum and psoas muscle, is often regarded as a strumous disease; and when the contents of the abscess are found to contain flakes of a curd-like matter, somewhat resembling white of egg, a substance peculiar to scrofulous abscesses, no one can doubt that the complaint is connected with this constitutional affection.—(See *Lumbar Abscess*.) The chronic enlargement of the thyroid gland is sometimes considered as scrofulous; but, though patients with this affliction, very often have, at the same time, other complaints, which are unequivocally strumous, though the enlargement of the thyroid gland most frequently commences at an early period of life, like scrofulous diseases, and though like them it is sometimes benefited by the carbonate of soda, burnt sponge, and iodine, the opinion, I think, is rather on the decline.—(See *Bronchocele*.) Scrofula also frequently makes its appearance in the form of imperfect suppurations, in various parts of the body; the contents of such abscesses being a curd-like matter, and the skin covering them having an unhealthy red appearance, and a thickened doughy feel. The mesenteric glands are often found universally diseased and enlarged in scrofulous subjects; and, as all nutriment has to pass through these parts, before it can arrive in the circulation, we cannot be surprised at the many ill effects which must be produced on the system, when such glands are thus diseased. However, as I have already hinted, doubts are entertained by Dr. Henning, whether enlarged mesenteric glands are decidedly scrofulous; but if his sentiment be incorrect, I fear he has been led to adopt it by his particular theory, which limits the origin of scrofula to the superficial absorbent glands. Scrofula frequently makes its attack on the testicles.—(See *Testicles, Diseases of*.) The female breast is also subject to scrofulous tumours and abscesses.

According to Sir A. Cooper, scrofulous persons frequently have follicles on different parts of the body, incrusted with inspissated matter. He agrees with most other writers in considering the absorbent glands and joints as the parts most frequently attacked, especially the glands of the neck and mesentery. Various other parts of the body he enumerates as liable to it—the lungs, the brain, the eyes; but the heart, he believes, is never affected. The secreting glands, he also says, are rarely the seat of scrofula, at least the liver and kidneys; for the breast and testicle are exceptions.

Dr. Thomson believes, that more or less local inflammation occurs in every form and stage of scrofulous diseases. He observes, that the swellings are very often from the first attended with a sensible increase of heat and redness, and that the pain, though seldom acute, is always present in a greater or less degree. Pressure on scrofulous swellings never fails to create pain; and the temperature of the skin covering them, is usually two or three degrees higher than that of the contiguous parts.—(*Lectures*, *&c. p.* 131.)

Scrofulous inflammation (as Mr. John Burns observes) is marked by a soft swelling of the affected part, which very frequently is one of the lymphatic glands. The covering or coat of the gland becomes slightly thickened, and its substance more porous and doughy. The swelling increases, and the doughy feel changes by degrees into that of elasticity, or fluctuation, and a firm, circumscribed, hardened margin, can be felt round the base of the tumour. The skin is slightly red. If, at this time, an incision or puncture be made, either no matter or very little is evacuated; the lips of the wound inflame and open, displaying a sloughy-looking substance within; and between this and the skin a probe can often be introduced for some way all round. It, however, the disease should have advanced farther, then there is very little elasticity in the tumour; it is quite soft, rather flaccid, and fluctuates freely; the skin becomes of a light-purple colour and small veins may be seen ramifying on its surface. Some time after these appearances, the skin becomes thinner at one particular part, and here it is also generally rendered of a darker colour. It afterward bursts, and discharges a thin fluid, like whey, mixed with a curdy matter, or thick white flocculi. The redness of the skin still continues; but the aperture enlarges as the tumour subsides, and thus a scrofulous ulcer is produced. The margins of this kind of sore are generally smooth, obtuse, and overlap the ulcer; they are of a purple colour, and rather hard and tumid. The surface of the sore is of a light-red colour; the granulations are flabby and indistinct; and the aspect is of a peculiar kind, which, says Mr. Burns, cannot be described. The discharge is thin, slightly ropy, and copious, with curdy flakes. The pain is inconsiderable. When this ulcer has continued for some time, it either begins slowly to cicatrize, or, as more frequently happens, the discharge diminishes and becomes thicker. An elevated scab is next formed, of a dirty white or yellowish colour. This continues on the part a good while; and when it falls off, leaves the place covered with a small purple cicatrix. Mr. Burns adds, that the preceding description corresponds to the mild scrofula, or the *struma mansueta* of the old writers. Sometimes, especially if a bone be diseased below the ulcer, the sore has a more fiery appearance, the surface is dark-coloured, the margins soft, elevated, and inflamed, and sometimes retorted. The discharge is watery, the pain very considerable, and the surrounding skin inflamed. This has been called the *struma maligna*. Such overacting scrofulous sores are most frequently met with over the smaller joints, particularly those of the toes. Sometimes a scrofulous abscess, after it has burst, forms a sinus; the mouth of which ulcerates, and assumes the specific scrofulous appearance, while the track of the sinus still continues to emit a discharge. Scrofulous swellings are often disposed to subside in winter, and recur on the approach of summer; but this is not an invariable law. Glandular enlargements are very apt to become smaller, in a short time, in one place, while other glandular swellings originate with equal suddenness, somewhere in the vicinity of the former ones. Ulcers also very often heal upon the appearance of the disease in other parts.—(*Burns's Dissertations on Inflammation*, *vol.* 2, 1800.)

The glandular swellings which occur in syphilis, says Dr. Thomson, are of a more acute character than those which proceed from scrofula. They arise from the absorption of a specific poison; and they do not, like those of scrofula, admit of a spontaneous cure; a belief, however, now known not to be exactly correct.—(See *Venereal Disease*.) Chronic swellings of the lymphatic absorbent glands occur also in carcinoma; but these manifest little or no disposition to suppuration: they succeed most frequently to carcinomatous indurations, or ulcers existing in the neighbourhood of the glands affected; and they are accompanied in their progress and growth by a peculiar lancinating pain.—(*On Inflammation*, *p.* 135.)

With regard to the proximate cause of scrofula, medical men may be said to remain, even at the present day, in entire ignorance of it. After the ridiculous theory, referring scrofula to certain humours in the constitution, or chemical changes in the blood, had been exploded, the opinion gradually arose, that it was a disease of the lymphatic system; and, indeed, that the absorbent glands are often visibly the seat of its attack, when no changes are distinguishable in other textures, is a fact that admits of no dispute. I believe, at the same time, that whoever supposes scrofula to be exclusively confined to the lymphatic system, must have a very imperfect conception of what is really the case. On the contrary, I fully participate in the sentiments of Professor Thomson, already adduced upon this point, and in the belief of another modern writer, that strumous complaints "are not to be considered as dependent on disease of any particular system, as the lymphatic."—(*Lloyd*, *p* 10.) Such

writers as have fixed upon the absorbent vessels as the particular seat of scrofula, can throw no useful light upon its origin, by following up the theory, whether they imagine the cause to be obstruction of the vessels and glands, or take up the wild speculation of Cabani, that in scrofula the mouths of the lymphatics are in a state of increased activity, while the vessels themselves are in a state of atony; or the doctrine of Soemmering, that scrofula depends upon a passive relaxation and dilatation of the absorbents; or the hypothesis of Girtanner, that these vessels are in a state of increased irritability. The idea of obstruction being the cause has of late years been much on the decline; and that the convolutions of lymphatic vessels forming the glands are quite pervious, and may readily be injected, even when diseased, is a fact first demonstrated by Soemmering, which must weigh heavily against this opinion. Sir A. Cooper describes the disease as proceeding from congenital debility, which attends its whole course, and imparts to it a peculiar character, rendering the various processes of inflammation in it slow and imperfect.—(*Lancet*, *vol.* 4, *p.* 65.) Of the exciting causes, very little is also known. Mr. John Hunter remarks, that "in this country, the tendency to scrofula arises from the climate, which is in many a predisposing cause, and only requires some derangement to become an immediate cause, and produce the whole disease."—(*On the Venereal Disease*, *p.* 26.) The disease is remarked to be most common in females; in cold, damp, marshy countries, and in all places, near high mountains, where the temperature is subject to great vicissitude. "Nous voyons presque toujours (says Alibert), que les tumeurs et les ulcères se rouvrent au printemps pour se fermer ensuite vers la canicule."—(*Nosol. Naturelle*, *p.* 449.)

In the work quoted the last but one, Mr. Hunter takes notice of slight fevers, colds, small-pox, and measles, exciting scrofulous diseases. He observes, that in particular countries, and in young people, there will sometimes be a predisposition to scrofula; and that, in such subjects, buboes will more readily become scrofulous.—(*P.* 37.) In short, it was one of Mr. Hunter's opinions, that the venereal disease is capable of calling into action such susceptibilities as are remarkably strong, and peculiar to certain constitutions and countries; and that, as scrofula is predominant in this country, some effects of other diseases may partake of a scrofulous nature.—(*P.* 96.) Mr. Hunter, speaking of venereal buboes, mentions his having long suspected a mixed case, and adds, "I am now certain that such exists. I have seen cases where the venereal matter, like a cold, or fever, has only irritated the glands to disease, producing in them scrofula, to which they were predisposed. In such cases, the swellings commonly arise slowly, give but little pain, and seem to be rather hastened in their progress, if mercury is given to destroy the venereal disposition. Some come to suppuration while under this resolving course; and others, which probably had a venereal taint at first, become so indolent that mercury has no effect upon them; and, in the end, they get well of themselves, or by other means.—(*P.* 269.) For such buboes, Mr. Hunter used to recommend sea-bathing; and, in case of suppuration, poultices made of sea-water.

Sir A. Cooper observes, that the predisposing cause of scrofula is congenital, or original fault of constitution. The exciting causes, he says, are whatever tends to produce or increase debility, such as fever from diseases of a specific kind, like measles, scarlet fever, and small-pox. He notices the greater frequency on this account of scrofulous cases some years ago, when the advantages of vaccination were not known; and the importance of this practice to society, if it had no other recommendation.—(See *Lancet*, *vol.* 4, *p.* 70.)

In the words of a well-informed Professor, scrofula readily forms an alliance with almost every morbid affection, occurring either from external injury, or from internal disease; it modifies the appearance of other diseases, and seems to convert them gradually into its own nature. Indeed, there are few of the local inflammatory affections which occur in this country, in which the symptoms and effects of these affections, and the operation of the food and remedies employed for their cure, are not more or less modified by the degree of scrofulous diathesis, which prevails in the constitution of those who are affected by them. The scrofulous diathesis, wherever it exists, usually gives more or less of a chronic character to local inflammatory affections.—(*Thomson's Lectures*, *p.* 131.)

Sentiments corresponding to some of those already quoted are delivered by Dr. Alison; "The facts," says he, "which seem most decisive, as to the connexion of the scrofulous habit with general debilitating causes, may be recapitulated as follows:—1. The differences in the symptoms and progress of inflammation, when scrofulous, and when healthy, appear manifestly to indicate in the former case a languid state of the circulation, particularly in the capillary vessels of the diseased part. 2. The hereditary disposition to scrofula is chiefly transmitted from parents, and is mostly observed in children, who show evident marks of constitutional debility in other respects. 3. There is no state of the body, as every practitioner knows, in which scrofulous action is so easily excited, as the state of great and often permanent debility, which remains after severe febrile disease, continued fever small-pox, measles, scarlatina, or which follows the long-continued use of mercury, or accompanies amenorrhœa. 4. The season at which scrofulous diseases have been observed to prevail most in this climate, is not that when cold weather has recently set in, and is most productive of disease in general, but the end of the winter and the spring; and they are then chiefly observed in those young persons who have manifestly lost strength during the continuance of the cold weather."—(*Alison, in Edin. Med. Chir. Trans. vol.* 1, *p.* 381.)

It has been the fashion of late years to ascribe the origin of a vast number of diseases to disorder of the digestive organs, little trouble being generally taken to consider, with any impartiality, whether the derangement of those organs may not be rather the common effect than the common cause of so many various diseases. Numerous circumstances tend to perpetuate the delusion into which young practitioners are falling upon this topic. They see various diseases, attended with dyspepsia, flatulence, loss of appetite, costiveness, and a torpid state of the bowels; they observe that such diseases and the latter complaints of the alimentary canal generally diminish together; that, when the functions of the stomach and bowels are deranged, any other diseases which the patient may be labouring under, either grow worse, or are retarded in their amendment; and, lastly, the treatment to which the theory leads, improves the health, by rectifying the state of the alimentary canal; and the sore, tumour, or other complaint, in the end, with the additional aid of time, nature, and other favourable circumstances, gets well. But, however simple, safe, and beneficial the practice may be, and plain as the facts are which lead to it, there is no proof that the other disease was truly a consequence of the disorder of the digestive organs. The latter symptom, I believe, is very frequently an effect mistaken for a cause, and perhaps always so in relation to scrofula. Besides, if it were to be assumed (as indeed it actually is), that in scrofula "there *always* is more or less disorder of the digestive organs, and *primarily of no other important function*," I do not see that we advance one step nearer the truth; because, as the same cause is generally assigned by gentlemen attached to this theory, for a vast number of other cases, we still remain in the dark as to the circumstances which make so many complaints of different kinds spring from one and the same cause. These circumstances, though buried in silence, are still the mystery—still the secret, which is desired; and if it be answered that the effect will only happen in particular constitutions, then we are brought back at once to the point from which we first started, viz. that scrofula is a disease depending upon some unknown peculiarity of constitution, congenital or acquired, and capable of being excited into action by various causes, as climate, mode of living, &c. However, lest I may not have attached sufficient importance to the doctrine of gastric disorder being the cause of scrofula, I feel pleasure in referring for the arguments in its support, to the writings of Mr. Abernethy, Dr. Carmichael and Mr. Lloyd, whose sentiments appear highly commendable as far as they tend to teach surgeons rather to place confidence in means calculated to improve the health in general, as the most likely mode of benefiting scrofulous patients, than to encourage foolish dreams about new specifics for the distemper. Thus

far I can follow these gentlemen safely; but no farther, except as a skeptic. However, perhaps none of the believers in the effect of disorder of the digestive organs mean to say, that such disorder is any thing more than one of the many exciting causes of scrofula; and with this qualification their theory may or may not be correct. It is the doctrine of Alibert, and indeed of nearly all writers: "ce sont les vices de la puissance digestive, qui préparent de loin les scrofules. Rien n'influe davantage sur leur développement que la mauvaise qualité des alimens," &c.—(*Nosol. Naturelle*, *p.* 449.) "Ajoutez à cet cause le séjour dans les habitations malsaines." But every explanation, even of exciting causes, remains unsatisfactory, as long as we find children living in the same air, under the same roof, and feeding and sleeping together, and clothed also exactly alike, yet only one or two of them become scrofulous, while all the rest continue perfectly free from the disease. Here, then, we are again compelled to return to predisposition, constitution, diathesis, and a congenital tendency to the complaint, as a solution of the difficulty. In short, then, respecting the etiology of scrofula little is known, except that certain constitutions probably have a congenital disposition to the disease; that such disposition may be increased or diminished by the operation of climate, mode of life, age, &c.; and that irritations of a thousand kinds may excite the disease into action, when the system is predisposed to it, by inexplicable causes. That climate has great influence cannot be doubted, when it is reflected, that the inhabitants of certain countries, in which the temperature is invariably warm, never suffer from scrofula. It is noticed by Sir A. Cooper, that the occurrence of scrofula is much promoted by climates, in which the change from cold to heat, and from heat to moisture, is particularly frequent, as is the case in this island. But though cold and moist climates have this effect, he remarks that persons living in the extremes of heat or cold are not affected. The disease, he says, is even arrested by cold and heat, uncombined with a damp atmosphere. On the other hand, numerous children who come from the East or West Indies to this country fall a prey to scrofula. He has also known some individuals from the South Sea islands die here of the same disease.—(*Lancet*, *vol.* 4, *p.* 67, 68.) The fact of the great influence of climate on scrofula is equally proved by the effect of the weather and seasons, for it is a common and a true remark, that in a mild dry atmosphere, and in summer time, the health of scrofulous persons generally improves, and whatever local complaints they may have get better, while on the contrary their disorder in winter is more difficult of relief, and either continues stationary, or becomes worse again. Hence, as Sir A. Cooper has justly remarked, the exact value of any proposed remedy for scrofula cannot be estimated, without reference to the time of year when it is tried. There can also be no doubt that, with age, the disposition to scrofula diminishes; for children much afflicted while young, frequently get quite well when they approach the adult state; and if a person remain perfectly free from every mark of a scrofulous constitution till the age of twenty-five, he may be considered as nearly out of all danger of the disease.

According to the calculations of Dr. Alison, scrofulous diseases are much more frequent in the inhabitants of great towns than in the agricultural population of any climate. This seems to him an unquestionable fact, and one that confirms the truth of the connexion of scrofula with debilitating causes.—(See *Edinb. Med. Chir. Trans vol.* 1, *p.* 383.)

TREATMENT OF SCROFULA.

"For the cure of scrofula (says Cullen), we have not yet learned any practice that is certainly or even generally successful. The remedy which seems to be the most successful, and which our practitioners especially trust to, or employ, is the use of mineral waters. But, he adds, in very many instances of the use of these waters, I have not been well satisfied that they had shortened the duration of the disease more than had often happened when no such remedy had been employed. With regard to the choice of the mineral waters most fit for the purpose, I cannot, with any confidence, give an opinion. Almost all kinds of mineral waters, whether chalybeate, sulphureous, or saline have been employed for the cure of scrofula, and seemingly with equal success and reputation; a circumstance which leads me to think, that if they are ever successful, it is the elementary water that is the chief part of the remedy. Of late, sea-water has been especially recommended, and employed; but after numerous trials, I cannot yet discover its superior efficacy."—(*First Lines of Physic*, *vol.* 4.) On the subject of mineral waters, Dr. Thomson very properly remarks, that they are now usually employed as purgative and tonic remedies, and not as specifics. In employing them it is often difficult to distinguish between the effects which they in reality produce, and those which are to be attributed to the slow operation of time, the season of the year, change of situation, alteration in the mode of life, or exercise in the open air.—(*Lectures on Inflammation*, *&c. p.* 195.)

In scrofulous diseases, Dr. Fordyce had a high opinion of bark; and he endeavoured to prove, that in cases of tumefied glands attended with a feeble habit and a weak circulation, it is a most efficacious medicine, and acts as a resolvent and discutient. He also brings forward a case in support of bark being a means of cure for ophthalmia strumosa.—(See *Med. Obs. and Inq. vol.* 1, *p.* 184.) Dr. Fothergill, in the same work, *p.* 303, writes in favour of the good effects of bark in similar cases; small doses of calomel being sometimes given with it.

Dr. Cullen considered the efficacy of bark in scrofula very dubious and trivial.—(*First Lines*, *&c. vol.* 4.)

According to Mr. Burns, bark has been frequently found useful in the cure of scrofulous inflammation, but more often of ulceration than tumefaction of the glands. But, says he, it does not appear to possess, by any means, that certain power of curing scrofulous affections, which is attributed to it by Dr. Fothergill and several other authors. He observes, that we are not to suppose it will infallibly cure scrofulous inflammation, or ulceration of parts, which, even when affected with simple inflammation, are very difficult of cure. If it be difficult to cure a simple inflammation or ulceration of a tendon, cartilage, or bone, we must not be disappointed if even a specific remedy for scrofula (were such ever discovered) should prove ineffectual in procuring a speedy restoration to health. Mr. Burns contends that bark is often ineffectual, because improperly administered. Given in small quantities, once or twice a day, it may prove a stomachic, and increase, like other tonic bitters, the power of the stomach, or the functions dependent on it: but in order to obtain the benefits of the specific action of bark, he maintains that it should be given in large quantities, for several weeks, with a good diet, air, and proper exercise.—(*On Inflammation*, *vol.* 2, *p.* 371.) Dr. Thomson does not believe that bark or iron has any specific virtue in curing scrofula; but he admits that either of these medicines may sometimes prove useful in amending the tone of the digestive organs, when given after, or occasionally along with, a course of purgative mineral waters.—(*Lectures*, *p.* 197.) When bark is prescribed, the sulphate of quinine is one of the best formulæ, as least likely to disagree with the stomach.

As far as I can judge, Mr. White has with much reason recommended paying attention to such circumstances as may have effect in preventing the disease, viz. air, cleanliness, exercise, and diet. He mentions cold-bathing among the preventives of struma, and speaks of sea-bathing as being the best. He advises attention also to be paid to the manner of clothing children, keeping them more covered in winter than summer. He thought a great deal of sleep prejudicial; but this seems only conjecture.

In noticing the treatment of the disease, Mr. White states, that "the general idea of the struma is, that it is a disease of debility (a doctrine also inculcated by Sir A. Cooper); and, therefore, the great object is to invigorate the habit by every possible means; the chief of which are tonic medicines and sea-bathing. Some are of opinion, that in the case of young patients this should be continued during the summer months, every year, to the age of fourteen or sixteen. Many recommend it not only in the summer, but throughout the year; while others are for administering alteratives, principally the alkaline salts, with or without antimonials, and the different tonics, during the winter: and the sea-water, and sea-bathing, or cold-bathing, during the summer, for a continuance of two or three years from the commencement of the disease: with this

general observation, that they will outgrow the complaint." Mr. White mentions, as the chief external means, fomentations and poultices of sea-water. With respect to regimen, some recommend a milk and vegetable diet; others animal food and fermented liquors. Sir A. Cooper in particular, who regards the disease as connected with congenital debility, strongly recommends a nutritious diet of animal food, in preference to one of vegetables.—(*Lancet, p.* 71.)

Mr. White maintains, that the preceding plans of treatment are not in general efficacious, though in some instances they may prove useful. "In early affections of the lymphatic glands (says this gentleman), and from the want of a pure air and proper exercise, where children are delicate and irritable, a change of situation to the seaside, together with bathing, when they have acquired some strength, must be exceedingly proper; and in gross plethoric subjects, who have diseased lymphatics, from improper feeding, and want of necessary exercise, a journey to the seacoast may be very useful, particularly if the salt water is drank often, and in a sufficient quantity to become purgative. This, with the novelty of their situation, which may naturally produce an increase of exercise, might answer every expectation; but these are the kind of cases that with a very little attention are easily cured."—(*White on the Struma, edit.* 3, *p.* 104.)

The conclusion to which Mr. White's remarks upon this part of the subject tend is, that sea-bathing only deserves praise as a preventive, and in the early stages of the disease. He particularly condemns cold-bathing for poor, weakly, debilitated children, whose thin visages, enlarged bellies, and frequent tickling cough, sufficiently indicate diseased viscera: such do not recover their natural warmth, after cold-bathing, for hours, and their subsequent headache, livid lips, and pale countenance, are sufficient marks of its impropriety.—(*P.* 107.)

Dr. Cullen entertained a very favourable opinion of cold-bathing, since he affirms that he had seen scrofulous diseases more benefited by it than any other remedy.—(*First Lines of Physic, vol.* 4.)

"Cold-bathing, especially cold sea-bathing (says Mr. Russell) is a remedy universally employed in scrofula, and I believe with great advantage in many cases; for it not only appears to improve the patient's general health and strength, but likewise to promote the detumescence of enlarged glands, and the resolution of indolent swellings in the joints, even after they have attained a considerable size, and have existed for a great length of time. But in order that cold-bathing may be practised with safety and advantage, the constitution must have vigour to sustain the shock of immersion without inconvenience. If the immersion be succeeded by a general glow over the surface of the body, and the patient feels cheerful, and has a keen appetite, we may conclude that the cold bath agrees with him; but if he shivers on coming out of the water, continues chill, and becomes drowsy, we may be assured that the practice of cold-bathing does no good, and had better be omitted.

"In estimating the comparative merit of cold-bathing and warm-bathing in the cure of scrofulous complaints, my own experience, together with the result of different conversations on the subject with some of the most judicious practitioners of my acquaintance, would lead me to bestow much more commendation on the effects of warm-bathing. I should not even be inclined to circumscribe the practice to cases of emaciation and debility, since, from observation, I am fully satisfied with regard to the beneficial effects of the warm bath to patients of plethoric constitutions, who were much affected with swelled scrofulous glands. Several of those instances occurred in young women, about the prime of life, who were in all respects healthy and vigorous, abating the swellings of the glands and those symptoms of distress which were connected with fulness of blood.

"The sensation of the warm bath is exceedingly grateful to most patients, and the practice is universally safe. It may be employed at all seasons of the year, and in all weather, without danger or inconvenience: the risk of suffering from exposure to cold, immediately after immersion in the warm bath, having been much magnified by prejudice. There is not even any good reason to believe in the existence of such a risk. The precautions, however, which are employed to avert it, are perfectly innocent; and, provided they do not impose any unnecessary and incommoding restraints upon the practice, may be encouraged, so far as to relieve the patient's mind from uneasiness and groundless apprehensions.

"It requires many weeks, and sometimes several months, to ascertain the full effects of warm-bathing in relieving scrofulous complaints; but as the practice is not attended with any inconvenience, nor followed by any bad consequence, there can be no reason to intermit the course till the trial is completely satisfactory; and I am convinced that the practice of warm-bathing in cases of scrofula will be more universally adopted after the knowledge of its beneficial effects are more widely diffused.—(See *Russell's Treatise on Scrofula.*)

Nothing can be more satisfactory (says Professor Thomson) than the evidence which is on record of the efficacy of the muriate of soda, as it exists in sea-water. In reading this, one only wonders how so efficacious a remedy should ever have fallen into neglect.—(*P.* 196.) In a subsequent passage, however, the same gentleman evinces only a limited confidence in this means of relief. "Local sea-bathing, both cold and warm, has often appeared to be of use in procuring the resolution of scrofulous swellings. The temperature of the bath must always be varied according to circumstances, according to the season of the year, the strength and habits of the patient, and the particular effect which the bath seems to produce. It is at all times difficult to distinguish between the effects immediately arising from the application of salt water to the body, and those which arise from the increased warmth of temperature in the bathing seasons of the year; from the exercise which patients going to sea-bathing generally take in the open air; from the change of situation and amusements; and, among the poorer classes, from the more nourishing diet and exemption from labour in which they are usually permitted to indulge during their residing at sea-bathing quarters. It is not improbable, that those living on the seacoast, who become affected with scrofula, would, for similar reasons, derive equal benefit by going from the seacoast to reside for a time in the interior of the country."—(See *Thomson's Lectures, &c. p.* 203, 204.) A still later writer declares his belief, that cold sea-bathing has no *specific power* over the disease.—(*Lloyd on Scrofula, p.* 43.) Yet the plain surgeon in search of practical truths will not care whether any plan has a *specific power* or not over a complaint, if that disorder is sometimes relieved by it. And that this is the fact is admitted by Mr. Lloyd, when he says, "cold sea-bathing, however, is certainly useful, when judiciously applied," &c. &c.—(*P.* 44.)

With regard to electricity, Mr. White thinks it useful, when from length of time the enlarged glands have acquired a degree of hardness and insensibility.

Mr. White, after enjoining attention to air, exercise, and diet, as promotive of a recovery as well as a preventive of the disease, proceeds to explain his own practice. The first external symptoms, such as swellings of the lips, side of the face, and of glands under the chin and round the neck; also other symptoms usually considered as strumous, viz. roughness of the skin, eruptions on the back of the hand and different parts of the body, redness and swelling of the eyelids and eyes, are accompanied, according to Mr. White's conceptions, with an inflammatory diathesis, though seldom such as to require bleeding. Calomel is the medicine which this gentleman recommends for the removal of the foregoing complaints. It is not to be given in such quantities as to render it a powerful evacuant, either by the intestines or any other way; but in small doses at bedtime. Thus, says Mr. White, "it remains longer in the intestinal canal, a greater quantity is taken into the habit, and the patient is less susceptible of cold than when taken in the daytime. The first and perhaps the second dose may prove purgative, which is in general a salutary effect; but afterward, the same quantity will seldom do more than is sufficient to keep the body open; and should it fail of answering that purpose, I have usually recommended some gentle purgative every third or fourth morning, according to circumstances. If there should be a prevailing acidity, a few grains of the sal sodæ, magnesia, or some testaceous powder, may be added to the medicine. By this simple method (continues Mr. White) most of the symptoms before mentioned will, in a short time, disappear; but if the tumours

should continue hard, and retain their figure without dividing into smaller ones, we may derive some benefit from external applications, particularly the steam of warm water. I have used a variety of medicinal herbs with success; but am inclined to believe that the advantage was particularly derived from warm water, &c. At other times, I have stimulated the part affected with electricity, insulating the patient, and drawing sparks from the tumour, until a slight degree of inflammation was excited. After the application of the steam, or the use of the electrical machine, I have sometimes rubbed a little of the unguentum mercuriale into the tumour and neighbouring parts, or applied the emplastrum saponaceum or mercuriale cum ammoniaco over the swelling, or a liniment with camphor, ol. olivarum, and sp. terebinth." Mr. White adds, that in such cases, if the tumours should suppurate and burst, the parts will, in most instances, heal without much trouble. For eruptions on the head, he recommends applying the ung. saturn. album camphoratum, or the cerat. alb. cum hydrarg. præcip. alb. For the roughness of the skin, which is generally followed by eruptions, he also advises the liquor plumbi acetatis dilutus, aqua calcis, solutions of sal tartar. or of the hydrarg. mur., as outward applications. "This last (says Mr. White) will seldom fail to check the progress of the complaint, and, dry the sores; and, in the quantity of ten or twelve grains to a quart of warm water, the use of it will not be productive of any pain. If the eruption should ulcerate, and require any unctuous application to prevent the adhesion of the linen, the ointment before mentioned may be applied; the best remedy will be warm-bathing, and, when practicable, the sea-water claims a preference."—(*P.* 114.) The author next mentions his having occasionally recommended the vinum antimoniale, tartarum emeticum, decoctum lusitanicum, decoctum lignorum, or sarsaparillæ; and that he sometimes found advantage derived from artificial drains. We need not detail this gentleman's mode of treating affections of the eyelids, as notice is taken of scrofulous diseases of the eye and eyelids in the articles *Ophthalmy* and *Psorophthalmy*.

For the cure of indurations in the breast, remaining after mammary abscesses, Mr. White speaks very highly of the effects of the steam of warm water; and cautions us against indiscriminately employing calomel, which will often affect the mother little, but the child violently. Mr. White mentions his employing a small tin machine, large enough to hold a pint and a half or two pints of boiling water. From the top proceeded a narrow tube, ten or twelve inches long, through which the steam passed. Near its end, which was moveable and curved, was a joint, for the greater convenience of directing the steam to the diseased parts. The water was easily kept boiling by means of a lamp under the machine. Mr. White says that the steam should be employed twice or thrice a day, and a piece of flannel or skin afterward applied. The body should also be kept open. In obstinate neglected cases, mercurial preparations, according to Mr. White, must likewise be given, and if they affect the child much, suckling should be suspended.—(*P.* 117, 118.) For chronic swellings of the breast, suspected to be scrofulous, I would here particularly recommend a trial of iodine, which should be used both externally and internally. —(See *Iodine*.)

When the glands of the neck or other parts of the body tend to a state of suppuration, it is very slowly, the skin appearing uniformly thin and of a deep-red colour, and the tumour seeming flaccid. In such cases, Mr. White recommends the use of the lancet or caustic; for if no artificial opening is made, it will be a long time before the skin gives way; and when it does, the aperture will not only be very small, but often unfavourable in its situation. Mr. White adds, that the contents will often be more like mucus than pus, or like a mixture of both; and the discharge will continue for a great length of time if no remedy is applied. He found a solution of gum myrrhæ in aqua calcis, used as a lotion, and the ceratum saponaceum, or some similar outward application, the best method of treating this symptom.

We need not describe Mr. White's practice in the treatment of scrofulous joints, as the subject is fully considered in the article *Joints*. It appears, however, that he confirms the efficacy of stimulating applications, and pressure with bandages, when the fingers and toes are affected with strumous disease.—(*P.* 143.) What may be done in these cases by the external and internal use of idione, remains to be proved by farther experience; but it is certainly a medicine, the power of which in scrofula merits the fullest investigation.

Whoever compares the practice of Mr. White in administering calomel, occasional purgatives, the decoctum lusitanicum, sarsaparilla, &c., with the blue pill, sarsaparilla, and laxative treatment of the present day, will perceive no very material difference between them, especially when the stress which Mr. White laid upon attention to diet, clothing, &c., is taken into the account. Mr. Lloyd, who has detailed Mr. Abernethy's practice in scrofula, lays it down as an axiom, that "the disease is only to be cured by avoiding all sources of irritation, and restoring the natural and healthy functions of the digestive organs."—(*P.* 48.) By sources of irritation, Mr. Lloyd means exciting causes: the advice is therefore excellent, as far as it can be followed, or such causes are decidedly known. The restoration of the functions of the digestive organs is also a thing worth aiming at; and the only difference in my views from those of Mr. Lloyd is, that as I look upon the disorder of the digestive organs to be in general only a complication or effect of the scrofulous disease, ulcer, abscess, diseased joint, &c., and not the exciting cause, the treatment, when beneficial, becomes so only on the principle of improving the general health, by the removal or diminution of one of the most hurtful consequences of the original disease. It is hardly necessary to inform the profession that the treatment described by Mr. Lloyd, in addition to the usual advice about diet, clothing, the avoidance of damp and cold, and the utility of good air, exercise, &c., consists in giving the patient five grains of the pil. hydrarg. every night, and half a pint of decoct. sarsap. c. twice a day. And if, at a certain hour of the day, there has been no motion, recourse is had to opening medicines. This plan is pursued till the bowels become regular; and then, with a view of preventing a relapse of the bowels into their former state, Mr. Lloyd continues the exhibition of alterative doses of mercury for an indefinite time, the preference being given to the compound calomel pill, in doses of five grains every night. In children, the practice is exactly like that of Mr. White, viz. small doses of calomel with purgatives. When acidity prevails in the stomach, small doses of soda are commended; and when the stomach is weak, with loss of appetite, cinchona, steel, and mineral acids. A full diet, with porter and wine, is disapproved of, and, as already stated, not much confidence is placed in sea-bathing.—(*Lloyd on Scrofula*, *p.* 38.)

Crawford, Pinel, and others tried the muriated barytes in scrofulous cases.—(*Med. Communications*, *vol.* 2. *Nosogr. Philosophique*, *vol.* 2, *p.* 238.) It has the recommendation of the celebrated Hufeland. Mr Burns says, that the muriate of barytes has no effect on diseased glands; but that it is occasionally serviceable in scrofulous ulceration; though he adds that it deserves little dependence.—(*Diss. on Inflam. vol.* 2, *p* 372.) This gentleman recommends the following formula: ℞. Terræ ponder. salit. chryst. gr. x. Aq. font. aq. cassiæ, utriusque ʒ iij. Syrup. aurent. ʒ ij. Half an ounce may be given at first, twice or three times a day, and gradually increased to such quantity as the stomach can bear without sickness. At present, few practitioners have any faith in the anti-scrofulous virtues of the muriate of barytes; and, as Dr. Thomson remarks, it has had a much shorter-lived reputation than sea-water or its successor the muriate of lime.—(See *Lectures on Inflammation*, *p.* 196.)

Fourcroy proposed the muriate of lime; but its efficacy is very doubtful and inconsiderable. "Professor Thomson (says Mr. Russell) has favoured me with the following observations on the effects of muriate of lime He employed muriate of lime in various cases of scrofula, without having derived benefit from it in a single instance. Some patients, indeed, he admits, got well while under a course of muriate of lime; but then he had no reason to ascribe the cure to the effect of the medicine. In other cases on the contrary, the muriate of lime produced severe sickness and suppression at the stomach, and the patients got daily worse till the muriate of lime was intermitted and other medicines employed. The relief experienced from the intermission of the muriate of lime, left no doubt with regard to the injurious effects which the use of it had pro-

duced; and, from extensive experience and accurate observation on the subject, Professor Thomson is satisfied that muriate of lime is attended with prejudicial effects in many cases of scrofula."—(See *Russell's Treatise on Scrofula.*) Since the publication of the earlier editions of this Dictionary, I have seen the muriate of lime given in several cases of scrofula; but without any beneficial effect on the disease. How long the muriate of lime will be permitted to enjoy its present fame, Dr. Thomson will not venture to say; but from what he has seen of its use, he imagines its reputation will only last till some other new remedy is proposed by those who are still sanguine in their hopes of discovering a specific for scrofula.—(*Lectures, &c. p.* 196.) Iron, given either alone or joined with the fixed or volatile alkali, also deserves very little confidence. Burnt sponge, millepedes, and sulphate of potassa have all been extensively tried: the first of these contains, as is now well known, a proportion of iodine, which is unquestionably a medicine of high value in the treatment of scrofula.—(See *Iodine.*)

The Mareschal de Rougeres employed a remedy, composed of iron filings, muriate of ammonia, subcarbonate of potassa, &c.—(*Journ. de Méd. tom.* 40, *p.* 219.)

Several narcotics have been tried, such as opium, hyoscyamus, the solanum dulcamara, &c.; but, though their virtues against scrofula have been sometimes cried up very highly, the moderns have lost all faith in them. The attention of the public to the effects of cicuta, in cases of cancer and scrofula, was first particularly excited by the accounts of its virtues published by Baron Stork.

Fothergill also praises cicuta, and perhaps, next to iodine, and soda joined with rhubarb and calumba, it is as good an internal medicine as can be tried; but it is far from being generally efficacious. It is highly deserving of recommendation for irritable scrofulous ulcers. There is now not the least doubt, however, that the statements of Baron Stork were greatly exaggerated. He considered cicuta indicated, whenever obstructions and tumours existed; and under this treatment, he says that he found the swellings melt away like ice. What is extraordinary, every sort of tumour yielded to cicuta. But (as Dr. Thomson judiciously remarks) universal success is always one of the most suspicious circumstances which can be mentioned in the history of the effects produced by any new remedy.—(*Lectures, &c. p.* 199.) Dr. Cullen frequently employed hemlock, and sometimes found it useful in discussing obstinate swellings; but, he says, it also frequently disappointed him, and he never saw it dispose scrofulous ulcers to heal.

With regard to mercury, we have already noticed that calomel was much employed by Mr. White. Some have exhibited the sublimate, others the acetate, of mercury. All these preparations have been at times conjoined with cicuta, antimony, &c. Calomel is, perhaps, the best mercurial preparation in scrofulous cases; but mercury, given internally with any view of exciting salivation, is justly deemed hurtful by all the best practitioners. As an alterative, and an occasional purgative, it is undoubtedly a good medicine for strumous patients. Mercury was much disapproved of by the celebrated Cullen as a medicine for scrofula. As a distinguished Professor observes, "From the great apparent similarity of the symptoms, progress, and seats of scrofula to those of syphilis, and from the well-known effects of mercury in curing syphilis, it need not seem strange, that medical men should have been a little obstinate in their attempts to obtain benefit from the use of mercury in scrofula. These expectations are in general abandoned, and mercury is now given for the cure of scrofula as a purgative only. A long-continued or improperly-administered course of this medicine has often been known to aggravate all the symptoms of scrofula; and, in many instances, to excite these symptoms in persons in whom they did not previously exist."—(See *Thomson's Lectures on Inflammation, p.* 194, 195.)

Mr. Burns thinks the nitrous acid has some effect in promoting the suppuration of scrofulous glands and tumours, and disposing ulcers to heal. He says, two or three drachms may be given every day for a fortnight; but if in this time it should do no good, its employment ought to be discontinued. The mineral acids diluted with water (says Professor Thomson), are often used with views similar to those which guide us in the employment of tonic remedies. Their medicinal powers appear to be nearly the same; but the nitric acid has of late been preferred, particularly in the scrofulous affections which are sometimes induced by the action of mercury.—(*Lectures, &c. p.* 197.)

The pills containing carbonate of soda (see *Pilulæ*), and the different soda waters sold at the shops, have repute for their good effects on scrofulous constitutions and diseases. A spirituous infusion of gentian, into six ounces of which are put thirty-six grains of the carbonate of soda, or the same quantity of the carbonate of ammonia, is a medicine highly spoken of by Richerand for scrofulous cases.—(*Nosogr. Chir. t.* 1, *p.* 184, *ed.* 4.)

Potassa, in large doses, with mercurial frictions, is the practice lately extolled by Mr. Farr; but it appears to me that mercury and potassa had been repeatedly tried, long before this author delivered his sentiments to the public; and that such practice cannot be justly called a method for the eradication of this disease.—(See *Farr on Scrofula*, 8*vo. Lond.* 1820.)

According to Mr. Burns, eight or ten drops of hydrosulphuret of ammonia, given thrice a day, are useful in irritable strumous ulcers. The breathing of oxygen gas has been proposed; but of this plan I know nothing from experience; and as it now makes less noise in the world than formerly, I conclude that either its usefulness has been exaggerated, or the difficulty of the practice is too great to permit its extensive adoption.

The sentiments of Dr. Cullen are decidedly against antimony. As a modern writer observes, no great dependence seems ever to have been placed in the use of diaphoretic medicines for the cure of scrofula. The different preparations of antimony, indeed, have been occasionally administered; but chiefly in cutaneous affections, supposed to be of a scrofulous nature. Guaiacum, sarsaparilla, sassafras, and mezereon, singly, and in combination, have all been supposed to be useful in the cure of scrofula; but they are now seldom given with this view, except in cases of scrofula combined with syphilis, or excited by the too free and injurious use of mercury.—(*Thomson's Lectures, &c. p.* 199.)

With respect to Alibert's practice among the vegetable bitters, he prefers the hop, burdock, gentian, and bark. He seems to have no confidence in specifics, like hemlock, belladonna, aconitum, &c. Neither does he express himself favourably of alkaline medicines, or the muriates of ammonia and barytes. However, he praises the good effects of steel medicines on enlarged glands. He affirms that he has seen most good derived from external means; aromatic fumigations in an apparatus prepared by the chemist Darcet. What he calls scrofulous eruptions, he covers with a strong solution of the nitrate of silver. Swelled glands he rubs with the antimonial ointment. He commends also change of air, and the avoidance of low, damp places; and speaks favourably of sea-bathing, sea-voyages, sulphureous mineral waters, and particularly of the good effects derived from the solar warmth. (See *Nosol. Nat. p.* 449.)

Sir A. Cooper, in his account of the treatment of scrofula, dwells more upon the good effects of air, exercise, and nourishment, than upon the virtues of physic. He asserts that there is no specific for the disease. Medicines, occasionally given for the improvement of the digestive organs, and regulation of the secretions, he admits, are useful; but attention to air, exercise, and diet he considers far more important. Sometimes he prescribes, once a week, or every ten days, two grains of calomel and eight of rhubarb, in order to restore the visceral secretions. A good tonic medicine, for a short time, he observes, is two grains of rhubarb, and from three to five of the carbonate of iron. Another, he says, is two of rhubarb, six of dried subcarbonate of soda, and ten of calumba, taken mixed with sugar. He recommends also a few grains of hydrargyrus cum creta, to be taken in the infusion of chamomile flowers at bedtime; or the oxymurias hydrargyri, in the proportion of a grain to two ounces of tincture of bark, of which a tea-spoonful may be taken twice a day in a glass of chamomile infusion; or, when costiveness prevails, the tincture of rhubarb may be substituted for that of bark. The liquor potassæ is also enumerated. But the medicines he prefers are

steel, with rhubarb and calomel, or the subcarbonate of soda, with rhubarb and calumba.—(*Lancet, vol.* 4, *p.* 94.)

As tonics of the highest merit, the sulphate of quinine, and the preparations of iodine, should also be remembered.

The local treatment preferred by Mr. White has been already described. I have only a few words to add concerning this part of the subject. Dr. Cullen states, that, in his practice, he had very little success in discussing incipient scrofulous tumours by topical applications; and that a solution of the saccharum saturni, though sometimes useful, more frequently failed. Dr. Cullen found the aqua ammoniæ acet. not more successful. "Fomentations of every kind (says he) have been frequently found to do harm; and poultices seem only to hurry on a suppuration. I am doubtful, if this last be ever practised with advantage; for scrofulous tumours sometimes spontaneously disappear, but never after any degree of inflammation has come upon them; and, therefore, poultices, which commonly induce inflammation, prevent that discussion of tumours which might otherwise have happened." Even when scrofulous tumours have advanced towards suppuration, Dr. Cullen thought, that hastening the spontaneous opening, or making one with a lancet, was hurtful.

With respect to ulcers, Dr. Cullen remarks, that escharotic preparations of either mercury or copper, have been sometimes useful in bringing on a proper suppuration, and thereby disposing the ulcers to heal; but they have seldom succeeded, and, more commonly, they have caused the ulcer to spread more. The escharotic from which Cullen saw most benefit result, was burnt alum mixed with some mild ointment. But this celebrated writer gives the preference to keeping the sores continually covered with linen wet with cold water in the daytime, and some ointment or plaster at night. He usually found sea water too irritating, and no mineral water better than common water.—(*First Lines of the Pract. of Physic, vol.* 4.)

Formerly, the extirpation of scrofulous tumours was advised; but this method is now considered as being, for the most part, injudicious and unnecessary, with the exception of diseased joints, and a few other parts, which frequently require being amputated, for the sake of saving the patient's life. Certainly no particular danger (generally speaking) would attend cutting out scrofulous glands and tumours: the objections to the plan are founded on the pain of the operation; on the number of such glands frequently diseased; on their often subsiding, either spontaneously or by surgical treatment; on the operation doing no good to the general affection of the system, &c. When, however, a scrofulous testicle, breast, or joint, seriously impairs the health, and endangers life, the very existence of the patient demands the immediate removal of the diseased part. Wiseman relates, that he was in the habit of cutting out scrofulous glands and tumours with great success; but, for reasons already alleged, most of the moderns think such operations in general unadvisable.

Caustics have been employed for the same purpose instead of the knife; but as they effect the object in view less certainly, more painfully and tediously, and cause extensive ulcers, they are disused by all the best surgeons of the present day.

Some authors have advised making issues, and keeping them open, in order to prevent any ill effects from the healing of scrofulous ulcers. Issues are certainly quite unnecessary for any purpose of this kind; but they are eminently useful as a part of the local treatment of scrofulous joints and abscesses, as we have more particularly explained in the articles *Joints*, *Lumbar Abscess*, and *Vertebræ*.

Mr. Burns notices, that issues have hitherto been chiefly used in diseases of the bones and joints; but he adds, that it is reasonable to suppose, that they ought likewise to be useful in the cure of enlargements of the glands and other scrofulous tumours, if inserted in the immediate vicinity of the part. The only objection to their use is the scar which they leave, and which, in certain situations, one would particularly wish to avoid. When the tumour is thickly covered with the integuments, the issue may be made directly over it, and kept open with the savine ointment. In other cases, a small pea issue or seton, may be inserted by the side of the tumour. This method would be objectionable for scrofulous glands in the neck, in consequence of the scar; but it might be employed when the mamma is diseased.—(*Dissertations on Inflammation, vol.* 2.) The late Mr. Crowther used to apply blisters to scrofulous swellings, and maintain a discharge from the part. And a more modern practice is that of producing irritation of the integuments, covering tumours and abscesses, by means of the tartar emetic ointment.—(*Alibert, Nosol. Naturelle, p.* 449; *Goodlad on Diseases of the Absorbents, p.* 162, *&c.*) The good effects of iodine upon scrofulous tumours, both as an internal medicine and local application, seem now to be exciting considerable attention. Certain indolent swellings of the testicle and breast, in particular, yield to this powerful medicine.—(See *Iodine.*) The profession, however, are still in want of some candid and accurate reports upon the subject, which is at present obscured by the exaggerations always attending the first introduction of a medicine, supposed to have power over any disease that has been found so little under the control of physic as scrofula. I beg, at the same time, the attention of every surgeon to the strong recommendations with which iodine has been brought into notice, and to its great medicinal powers, as already verified in bronchocele.—(See *Bronchocele* and *Iodine.*)

Preparations of lead; cloths dipped in cold water, sea-water, or weak vegetable acids; ether; sea-salt mixed with bile; the linimentum camphoræ; a mixture of ether and the linimentum opiatum; and hemlock poultices; form a long list of applications, which have been employed for scrofulous tumours.

According to Mr. Burns, moderate pressure, by means of adhesive plaster, conjoined with the application of cold water, is one of the best plans of treating mild scrofulous ulcers, when their situation admits of it. In other cases, he recommends applying a powder, five parts of which consists of cerussa acetata, and the sixth of burnt alum. A piece of dry lint is next to be applied, and a compress, with such a pressure as can be used. Benefit occasionally results from dipping the compress in cold water.

The ung. zinci is a good common dressing, when it is wished not to interfere much with the progress of the ulcer. The ung. hydrarg. nitrat. rub. and the ung. hydrarg. nitrat. are the best stimulating ointments. Poultices of bread and sea-water; solutions of alum, sulphate of copper, and the hydrarg. mur.; solutions of the nitrates of copper, bismuth, and silver; the recent leaves of the wood-sorrel bruised; lint dipped in lemon-juice, or vinegar and water; a mixture of mercurial ointment and ceratum saponis (*Scott on Chronic Inflammation, &c.*); are among the applications to common scrofulous ulcers.

For irritable sores, diluted hydrosulphuret of ammonia; ointments containing opium; carrot and hemlock poultices; a solution of opium; and carbonic acid gas; are commonly recommended.

The following are Mr. Russell's sentiments respecting the treatment of scrofulous ulcers: "Scrofulous complaints in general do not agree well with stimulant applications. In the treatment of scrofulous ulcers, under the ordinary circumstances of complaint, the simplest and mildest dressings answer best. When the patients are using a course of sea-bathing, it is usual to wash the sores with sea-water, over and above the momentary application of the sea-water during the immersion of the whole body. Cold spring water is likewise a favourite application with many practitioners; and from much observation, it appears that the operation of cold is well suited to counteract the state of inflammation which accompanies scrofulous sores. Preparations of lead are, upon the whole, very convenient and useful applications, provided the solutions be used in a state of sufficient dilution to prevent irritation. Liquid applications are applied by means of wet linen, which is renewed whenever it dries, so that the surface of the sore may be kept constantly moist, when under this course of management. Upon the same principle, simple ointment and Goulard's cerate furnish the best dressing in ordinary cases.

"Scrofulous congestions of a solid nature, in the more external parts of the body, are little adapted to the practice of local bleeding, unless they be attended with symptoms of inflammation; but as some degree

of inflammation is, in general, present during the incipient stage, it may be prudent to employ local bleeding in moderation at the commencement of the attack, although there may be no indication to persist in the practice, after the complaint has advanced farther in its progress. If, however, these congestions are more of an indolent nature, unaccompanied with heat or pain, there is no benefit to be expected from the local detraction of blood; warm fomentations, together with the use of stimulants, and a repetition of blisters, are the most serviceable class of remedies: such cases, too, are the best adapted to the use of friction as a discutient. Friction, indeed, has long been employed for this purpose; but of late years, it has been introduced to an extent, and with an effect, far beyond the experience of all former practice. As yet, it has been circumscribed to the practice of a very few individuals, with whom it is said to have performed very great cures; and if, upon the test of more extensive experience, it is found to answer its present high character, I shall consider the use of repeated frictions to be one of the most valuable improvements which have been introduced into practice in modern times. The safety and simplicity of the practice recommend it very strongly to favour, though I am afraid they are the very circumstances which retard its adoption by the public in general. I only regret that I do not feel myself entitled to give a decided opinion upon the subject from my own experience, though I have known some instances of successful cures; but the reports of success are so numerous and so well supported, that I am inclined to think very favourably of the practice.

"There is no substance interposed between the surface of the swelling and the hand of the person who administers the friction, excepting a little flour, to prevent the abrasion of the skin. The friction is applied regularly two or three hours every day, with great celerity, the hand being made to move to and fro one hundred and twenty times in a minute, and the course may require to be continued, without interruption, for some months."—(See *Russell on Scrofula.*) Here I would again recommend to the notice of surgeons, the external use of iodine, as perhaps possessing more efficacy than simple friction.—(See *Iodine.*)

I shall not enlarge upon this endless subject, which still stands in need of elucidation as much as any disease that can be instanced. The scrofulous affections of the joints are elsewhere explained.—(See *Joints.*) *Bronchocele*, *Iodine*, *Lumbar Abscess*, *Spina Bifida*, and *Vertebræ* are other articles containing matter connected with the preceding observations.

SCROTOCE'LE. (From *scrotum*, and *κήλη*, a tumour.) A rupture or hernia in the scrotum.

SCROTUM, CANCER OF. (*Chimney-sweepers' Cancer. The Soot-wart.*) This peculiar disorder, which commences as a wart-like excrescence, is described by Mr. Pott, as always making its first attack on, and its first appearance in, the inferior part of the scrotum; where it produces a superficial, painful, ragged, ill-looking sore, with hard and rising edges. He never saw it under the age of puberty. According to Mr. Earle's observations, it very rarely attacks persons under the age of thirty. Most of the cases seen by him, were in individuals between the ages of thirty and forty. He has seen three instances in subjects between twenty and thirty; but only one at the age of puberty. A single case is mentioned by Sir J. Earle, which happened in a child under eight years of age. I have seen one case in a boy not more than sixteen.—(*Med. Chir. Trans. vol.* 12, *p.* 299.)

In no great length of time, it pervades the skin and membranes of the scrotum, and seizes the testicle, which it enlarges, hardens, and renders truly and thoroughly distempered; from whence it makes its way up the spermatic process into the abdomen, most frequently indurating and spoiling the inguinal glands: when arrived within the abdomen, it affects some of the viscera, and then very soon becomes painfully destructive.—(*Pott.*)

Not only is the discharge from the sore very fetid, but the perspiration from the whole body has a very peculiar ammoniacal smell.—(*Earle, in Med. Chir. Trans. vol.* 12, *p.* 298.)

"Other people besides chimney sweepers (says Pott) have cancers of the same part; and so have others besides lead-workers the Poictou colic, and the consequent paralysis: but it is nevertheless a disease to which they are peculiarly liable: and so are chimney-sweepers to the cancer of the scrotum and testicles."

Workmen exposed to the fumes of arsenic, are said to be liable to a cancerous disease of the scrotum, resembling that which infests chimney sweepers. This is particularly the case with the smelters in Cornwall. —(See *Paris's Pharmacologia, p.* 89, *vol.* 2, *ed.* 5.) If the two diseases are precisely similar, the fact is parti-

cularly interesting with regard to the cause of the complaint, which has been referred to the irritation of soot, and this alone, in a supposed peculiar condition of constitution, not defined, nor indeed at all understood.

Mr. Pott, as we find, describes the disease as always beginning at the lower part of the scrotum: but there are exceptions. Sir James Earle has recorded an instance of its occurrence on the wrist of a gardener, who had been employed in distributing soot for the destruction of slugs; and some cases are said to have taken place on the face.—(*H. Earle, in Med. Chir. Trans. vol.* 12, *p.* 297.) One circumstance is noticed by the latter writer, which, if it prove generally correct, materially influences the prognosis and treatment: he says, "the inguinal glands are often enlarged, but they will generally subside on the removal of the diseased scrotum; clearly proving that the disease is not commonly communicated in the course of the absorbents."—(*P.* 298.) He knows only one exception to this statement; a case where a bubo formed, suppurated, and assumed the same characters as the primary affection in the scrotum.

If there be any chance of putting a stop to, or preventing this mischief, says Mr. Pott, it must be by the immediate removal of the part affected; namely, that part of the scrotum where the sore is; for if it be suffered to remain until the testicle is affected, it is generally too late even for castration. "I have many times made the experiment; but though the sores, after such operation, have in some instances healed kindly, and the patients have gone from the hospital seemingly well, yet in the space of a few months, it has generally happened, that they have returned either with the same disease in the other testicle or in the glands of the groin, or with such wan complexions, such pale leaden countenances, such a total loss of strength, and such frequent and acute internal pains, as have sufficiently proved a diseased state of some of the viscera, and which have soon been followed by a painful death."—(*Pott.*)

Mr. Earl's experience has taught him, that no topical applications nor internal medicines have the slightest influence over the disease. The scalpel, he says, is the only resource, and it may be employed with confidence provided the whole of the diseased mass can be removed. Even when the inguinal glands are enlarged, he inculcates the same practice. Also, when the testicle is affected, provided the spermatic cord is sound, he conceives, that it is right to give the patient the chance of recovering; and notwithstanding the discouraging results of Mr. Pott's operations in this stage of the disease, he has known the attempt succeed in two cases, in which no relapse had happened several years afterward.—(See *Pott's Works, vol.* 3, *ed. by Earle. Also, W. Simmons's Obs. on Lithotomy, to which are added Obs. on Chimney-sweepers' Cancer*, 8vo. *Manchester*, 1808. *H. Earle on Chimney-sweepers' Cancer, in Med. Chir. Trans. vol.* 12, *p.* 296, *&c.*)

SCROTUM, *Sarcomatous Thickening and Enlargement of.* The investigations of Baron Larrey lead him to believe, that cases of enormous growth of the scrotum are endemial in warm countries, or, at least, that they are seldom observed in cold climates; since most of the examples which have been seen in Europe came from Asia and Africa. The scrotal tumour of Delacroix, formerly minister of external relations, says Larrey, is perhaps the only well-authenticated instance of the origin of such a disease in our own climate; and it was also much smaller than the instances related in the Ephemerides German. for the year 1692, in the surgical writings of Dionis, in the 9th vol. of the Bibliothèque de Médecine, and those which Larrey was surprised to meet with in Egypt. The smallest of these latter, after they had attained their full size, weighed more than 25 kilograms (between 60 and 70 pounds).

Several cases of this curious disease are recorded by other writers, particularly by Dr. Cheston, Dr. Titley, and the celebrated Sandifort. I lately saw, in Mr. Abernethy's museum, a considerable fleshy substance, which was a portion of diseased scrotum.

In the cases which Larrey had an opportunity of seeing in Egypt, the fleshy mass, into which the scrotum was converted, was broad below, and suspended from the pubes by a sort of pedicle. "Externally (as Larrey observes), the tumour presents rugosities of different sizes, separated by particular lines, or sinuses, to which the mucous cryptæ and roots of the hairs correspond. Upon a large portion of its surface, especially when the case is of long standing, yellowish scaly crusts are always seen, the detachment of which constantly leaves so many small herpetic ulcers, emitting an ichorous discharge. The tumour is indolent and hard at some points, but softish at others. It may be handled and pressed in different directions, without the least pain. The patient is only incommoded by its weight, and the impediment which it causes to his walking well. Hence, he is necessitated to employ a suspensory bandage. In consequence of the situation of the urethra, the urine dribbles over the swelling; but without causing any excoriation. In most of the cases, seen by Larrey, the spermatic cord and testicles were in the natural state, situated at the sides and at the root of the swelling. The spermatic vessels, however, were somewhat enlarged and elongated. All the patients were likewise more or less affected with elephantiasis.

Baron Larrey attempts to explain the causes of the complaint in Egypt, but, as I think, without any degree of success. As the affection is seldom seen in cold countries, climate has certainly a chief effect. Employments which keep persons a good deal in a sitting posture; the loose breeches worn by the Egyptians, and the consequently pendulous state of the scrotum; diseases of the humours, and particularly itchy pustules, on the part, an ordinary consequence of syphilis in that country; bad regimen; abuse of venery; and the immoderate use of the warm bath; are merely conjectures, which will not bear the test of reasoning.

The enormous magnitude which this sort of disease may attain is almost incredible. The case recorded in the Ephemerides German. weighed about a hundred kilograms, or more than two hundred weight. Another, described by Larrey, was calculated to weigh about one hundred and twenty pounds; and this surgeon likewise saw in Egypt ten or twelve more instances, nearly as large, and all of the same character.

A very curious example, in which a similar disease affected the labia pudendi in a surprising degree, is also detailed by Larrey. The woman was a native of Cairo.

In the early stage of the disorder, we may try preparations of antimony combined with sudorifics; drinks acidulated with sulphuric acid, lotions containing the same acid, or the oxymuriate of mercury, the oxyde of copper, or the muriate of ammonia. These means are to be assisted by a gradual, uniform compression of the whole tumour. In one case, incisions, and the application of caustic, proved of no service, and Larrey very properly condemns such experiments.

When the disease resists every plan tried for its relief, and its increase renders the patient's life irksome and wretched, the extirpation of the tumour with a knife becomes proper. In this proceeding, the chief skill consists in doing no injury to the spermatic cords and testicles, which are generally perfectly sound. As the substance of the swelling is not furnished with large vessels, the hemorrhage need not be feared. Care must also be taken not to injure the corpora cavernosa penis, and the urethra. After the operation, the skin is to be brought over the exposed testicles as much as possible, with adhesive plaster and a bandage.

M. Delonnes successfully removed the diseased mass in the celebrated case of the French minister Delacroix, and Larrey performed the same operation with success when he was in Egypt. Dr. Titley, of the island of St. Christopher, also cut away such a tumour, which weighed seventy pounds, and the patient, who was a negro, and also affected with elephantiasis, speedily recovered.—(See *Med. Chir. Trans. vol.* 6, *p.* 73, *&c.*)

It is probable that some of the cases, which occur in warm countries, are analogous to the elephantiasis; but I do not believe that the scaly incrustations which are represented by Larrey as occurring in the cases which he saw in Egypt, have been always noticed in the instances which have taken place in colder countries. Nor, indeed, did they take place in the instance recorded by Dr. Titley, the surface of the tumour having been quite smooth.—(*Larrey, Mém. de Chir. Militaire, t.* 2. *p.* 110, *et seq. Richerand, Nosographie Chir. t.* 4, *p.* 314, *&c. edit.* 4. *Delonnes's Memoir. Dr. Cheston's Case, &c. Med. Chir. Trans. vol.* 6.)

SEARCHING. The operation of introducing a metallic instrument, through the urethra, into the bladder, for the purpose of ascertaining whether the patient has a stone or not.—(See *Sounding.*)

SETON. A kind of issue, usually made by means of a flat needle, from half an inch to nearly an inch in breadth. The needle is commonly a little curved, but if straight, it would be better calculated for the purpose. From the point to its broadest part it is double-edged, and behind it has a transverse eye, through which a skein of thread, or silk, of exactly the same breadth as the needle, is placed.

A fold of skin is to be pinched up at the part where the seton is designed to be made, and the needle is to be pushed through it, together with the skein of thread, which is first dipped in sweet oil. The instrument is not to be introduced too low into the base of the fold, nor too high near its edge. In the first case, the muscles and parts which ought to be avoided might be wounded; in the second, the interspace between the two wounds would be very narrow, and the seton soon make its way through it.

When no seton-needle is at hand, the fold of the skin may be punctured with a lancet, and the skein of thread introduced by means of an eye-probe. A seton may be applied almost to any part of the surface of the body, when circumstances require it: but one of its openings should always be made lower than the other, that the matter may readily flow out. The skein of thread is to remain untouched for a few days after the operation, until the suppuration loosens it. Afterward the part of the thread nearest the wound is to be smeared with oil, white cerate, or any digestive ointment, and drawn under the fleshy interspace between the two wounds, and what was there before is to be cut off. The seton is to be drawn in this manner once or twice a day, according as the quantity of matter may require. A new skein of silk or thread is to be attached to the preceding one as often as necessary. Care is to be taken to keep the thread on the outside of the wound well covered, and free from the discharge, which would make it stiff and hard, and apt to occasion pain and bleeding on being drawn into the wound. If the discharge should be deficient in quantity, powdered cantharides may be mixed with the digestive ointment. A neater and less troublesome kind of seton, is that in which a thin, smooth slip of elastic gum is employed, instead of silk. The elastic gum tape is generally about four inches long, and half an inch wide: the needle for conveying it through the integuments has no eye, but takes hold of it in the manner of a pair of forceps. This kind of seton has the recommendations of being less painful than the common one, more cleanly, and does not require the repetition of the disagreeable operation of changing the silk. When it is wished to render it more irritating, the elastic gum slip may be drawn a little out of either opening, and smeared with savine ointment. I feel much obliged to the late Sir Patrick M'Gregor, for reminding me of this improvement, which is derived from the French.

SHINGLES. See *Herpes*.

SIGHT, DEFECTS OF. There are persons who, from their infancy, are incapable of distinguishing one colour from another. A man who was affected with this infirmity, could not distinguish green at all. Green and red appeared to him the same. Yellow and blue he could discern very well. With regard to dark red and dark blue, he frequently made mistakes. In other respects, his vision was sound and acute. The father of this patient was afflicted with the same infirmity. The mother and one sister were free from it. Another sister and two of her children had it. The patient himself had two children who did not labour under the disorder.—(See *Phil. Trans. vol.* 68, *part* 2.) Another subject, whose eyes were in other respects healthy, and whose eyesight was sharp, could not distinguish a dark green from a dark red.

An interesting example of this curious imperfection of vision has been published by Dr. Nicholl, of Cowbridge.—(See *Med. Chir. Trans. vol.* 7, *p.* 477, *&c.*) The subject was a healthy boy, eleven years of age, whose eyes were gray, with a yellow tinge surrounding the pupil. He never called any colour green. Dark bottled green he called brown. He could distinguish light yellow; but darker yellows and light browns he confounded with red. Dark brown he mistook for black. Pale green he called light red; common green he termed red. Light red and pink he called light blue. Red he called by its proper name. He could distinguish blue, both dark and light. On the mother's side, the boy had some relations whose sight was similarly affected. An interesting chapter on what is termed *coloured vision* may be read in a modern valuable work, to which I have great pleasure in referring.—(See *Wardrop's Essays on the Morbid Anatomy of the Human Eye, vol.* 2, *p.* 196, 8*vo. Lond.* 1818.)

Sometimes objects appear to the eye to be of a different colour from what they really are, not because there is any thing wrong in the eye itself, but in consequence of the unclear and coloured light by which the object is illuminated. Thus, for instance, a bad tallow candle, which emits a yellow flame, makes every thing appear yellow. When brandy is burning, all objects appear blue. In short, it is only by the light of the sun that any object can be seen in its clear, natural hue. In certain cases, the infirmity is owing to the transparent parts and humours of the eye, which do not happen to be of a proper colour. Thus, persons having the jaundice in a high degree see all things yellow, because the transparent parts of the eye are of that colour. When, in consequence of external violence applied to the eye, blood is effused, and the aqueous humour rendered red by this fluid, all objects seem to the patient to be red; and white, when the aqueous humour has been made of this colour by the couching of a milky cataract. Sometimes this defect in vision is ascribable to the duration of an impression. When one has surveyed a bright coloured object a long while, as for example, a bright red or yellow wall, on which the sun shines, that colour will often remain a good while before the eyes, although one may not be looking any more at an object of this hue. There are some eyes which seem much disposed to retain the impression of objects which are not very bright-coloured; but such a disposition always betrays great weakness and irritability of those organs. The most frequent cause of this defect in vision, is an irritation operating upon the optic nerves, so as to produce the irritability in them, which alone makes objects appear of one colour. The seat of such irritation, according to Richter, is also most commonly in the abdominal viscera, and the case demands evacuations, tonics, and anodyne medicines. But the disorder may also originate from other causes. The operation of bright-coloured or shining objects upon the eye sometimes has, for a certain time afterward, the effect of making objects of diverse colours appear to be moving before the eyes. In extreme terror or fright, things may also seem to have a different colour from their real one. The same often happens in fevers attended with delirium. A sudden exposure of the head to cold, at a period when it was perspiring much, in one instance, caused many-coloured appearances before the eyes; but the disorder subsided in a couple of days.—(*Richter, Anfangsgr. der Wundarzn. b.* 3, *p.* 523.)

Also, a healthy eye sees a distant object with uncertainty and error in a room or space, the extent, length, and breadth of which are unknown, when the size of the object itself is unascertained, and when there are few or no other objects intervening at a smaller distance between the eye and the thing looked at. The more numerous the objects are between the eye and the principal thing looked at, the more distant it is made to appear; the fewer they are, the nearer it seems to be. In a country covered with snow, and upon the sea, very distant objects appear to be close. The smaller an object is to the eye in relation to its known magnitude, the farther off it seems. The errors which the eye makes, in regard to the distance of objects, also tend to deceive. But there are certain cases in which the eye is almost entirely incapable of judging of the distance of objects. The first is, when the object of which we wish to ascertain the distance is looked at with only one eye. Hence all one-eyed persons, and persons affected with strabismus, are unable to judge well of the real distance of objects. However, they are only so for a certain time; and, by practice, they gradually acquire the faculty. Even when two eyes are employed, it requires some exercise in order to enable them to judge of the right distance of objects. Persons born blind, but who have their sight restored in both eyes by the operation for the cataract, are a long while incapable of judging of distances, and only obtain this power very gradually. Lastly, this infirmity is sometimes owing to an irritation affecting the optic nerves, whereby their sensibility is so altered, that distant objects make the impression upon them of near ones. In this circumstance all objects appear to the patient

closer than they really are. This is the only case which admits of being treated as a disease. The irritation producing the disorder is mostly seated in the abdominal viscera, and requires evacuations, and such medicines as invigorate the nerves. A suppression of perspiration is alleged to be sometimes a cause.—(*Richter, Anfangsgr. der Wundarzn. b. 3, p. 525.*)

A sound eye likewise does not always judge with accuracy and uniformity of the magnitude of objects. This may arise from three causes. In order to judge rightly of the size of any thing, its precise distance must be known; for the more remote it is, the smaller will it seem to the eye. Hence, any conjecture respecting the magnitude of an object, is constantly erroneous, unless the distance be ascertained. Size is invariably something relative. A single large object, surrounded by many small ones, always appears to be larger than it really is; et vice versâ. An object whose magnitude is known seems smaller than it actually is, when one has been a little previously looking at another that is still larger. Lastly, the refraction of the rays of light in the eye, by which operation an object is made to appear large or small, is not always accomplished in the same degree, as the eye is not at all times equally full and distended with its humours. Hence, at one time the same object will appear to the same eye, and at the same distance, larger; at another time smaller. Sometimes, however, the eye judges so erroneously of the magnitude of objects, that there is reason for regarding the case as an infirmity or disease. It is for the most part owing to a defective sensibility in the nerves, caused by some species of irritation acting upon the eye, and generally seated in the gastric organs. A man to whom every thing seemed one-half smaller and nearer than it really was, was cured by means of an emetic, bark, an issue, and valerian.—(*Leutin, obs. fascic.*)

Sometimes to the eye, under circumstances of disease, straight lines appear serpentine; perpendicular objects sloping; things standing upright, to be inverted, &c. The son of a distinguished artist began when seven years old to learn drawing under his father, who was much surprised to find all the objects which the young pupil represented drawn upside down. It was at first supposed, that the child might be practising this inversion of objects in joke; but he affirmed that the things were drawn exactly as they appeared to him, and there was no reason to doubt his word. Whenever an object was turned before he took a sketch of it, he represented it in the natural position, showing that the sensation received by the eye corresponded perfectly with the inversion formed on the retina. This state of vision ceased at the end of a year.—(See *Journ. Univers. des Sciences Méd. Fév.* 1828.) All the preceding cases are set down by Richter as depending upon a wrong sensibility of the nerves, occasioned by the effect of some irritation. The irritation, he says, may be of many kinds; but experience proves that it is mostly seated in the gastric organs. These defects of sight may generally be cured by first exhibiting emetics and purgatives, and afterward having recourse to remedies for strengthening the nerves—bark, oleum animale, valerian, issues, &c. One mark of a very weak and irritable eye is, when objects, after being looked at a good while, and presenting a right appearance, begin to move, swim about, mix together, and at length become quite undistinguishable. This principally happens when the objects regarded are small and strongly illuminated. Here such remedies, both general and topical, as have the effect of invigorating the nerves are indicated. However, sometimes the infirmity is partly owing to the operation of some species of irritation, which will require removal ere the tonic medicines and applications can avail. Indeed, in particular cases, the dispersion of such irritation is alone sufficient to accomplish the cure.

Sometimes all objects appear to the eye as if they were in a more or less dense mist. This defect in vision is always owing either to some slight opacity of one of the humours of the eye, or to excessive debility of the optic nerves.—(See *Richter, Anfangsgr. der Wundarzn. b. 3, p. 521, &c.*)

SINUS. A long, narrow, hollow track, leading from some abscess, diseased bone, &c.

SOUND. An instrument which surgeons introduce through the urethra into the bladder, in order to discover whether there is a stone in this viscus or not. The sound is made of highly-polished steel, that it may be well calculated for conveying to the surgeon's fingers the sensation of any thing against which its end may strike. It is also generally rather less curved than a catheter, so that its extremity may be more easily inclined to the lower part of the bladder, where the stone is most frequently situated.

SOUNDING. The operation of introducing the foregoing instrument.

Sounds are generally introduced much in the same way as catheters, either with the concavity towards the abdomen or the convexity; in which last method it is necessary, as soon as the beak of the sound has arrived in the perinæum, to bring the handle of the instrument downwards by a semicircular movement to the right, while the other end is kept as much fixed as possible. This is what the French term the coup or tour de maître; a plan that is often followed at the present day, though, except in very corpulent subjects, it has no particular recommendation.

When a patient is to be sounded, he is usually put in a posture very similar to that adopted in the lateral operation for the stone, with the exception that he is not bound in this position, as there is sometimes an advantage in making the patient stand up, in order that the stone may come in contact with the end of the sound. The instrument having been introduced, its extremity is to be turned and moved in every direction, when, if there be a calculus, its presence will usually be indicated by the collision against the beak of the sound.

Stones have sometimes been found in the bladder after death, although they could never be discovered with a sound while the patient was alive, suffering all the symptoms of the complaint. The celebrated French surgeon La Peyronie was thus circumstanced: he was so fully convinced of there being a stone in his bladder, notwithstanding neither he nor any of his friends could feel it with a sound, that, on his death-bed, he gave directions for ascertaining the fact. Hence, when the usual symptoms of a stone in the bladder continue, patients should be searched several times before a positive opinion is delivered respecting the nature of the disease. When, during the operation of sounding, all the urine has escaped from the bladder, the inner surface of this viscus comes into contact with the end of the sound, and such a sensation may be communicated to the surgeon's fingers as leads him to suspect that a fungus, or some other hardish extraneous substance is contained in the bladder. In such cases patients have actually been cut for the stone, when no foreign body whatever was present.—(See *Sabatier, Médecine Opératoire, t. 3, p. 127, 128, edit. 2.* See *Lithotomy.*)

SPE'CULUM. An instrument to facilitate the examination of parts, and also the performance of operations on them: thus we have specula ani, oculi, auris, uteri, &c.

SPHA'CELUS. (From *σφάζω*, to destroy.) Surgeons imply, by this word, complete mortification, which is mostly preceded by a stage of the disorder, termed *gangrene.* See *Mortification.*

SPICA. (From *σπάχυς*, an ear of corn.) A name given to a kind of bandage, in consequence of its turns being thought to resemble the rows of an ear of corn

In order to apply the spica bandage to the shoulder, the margins of the axillæ must first be protected from the effects of the pressure, by means of soft compresses, and the end of a common roller is then to be placed under the armpit, on the sound side. After conveying the bandage backwards, obliquely over the scapulæ, the surgeon is to bring it forwards over the injured shoulder. The roller is next to descend under the armpit, then be carried upwards again, and made to cross on the deltoid muscle It is now to be carried obliquely over the front of the chest, and under the opposite armpit, where the end of it is to be pinned or stitched. The bandage is next to pass across the back, over the part of the roller previously applied in this situation, and is to be conveyed round the head of the os brachii, so as to form a turn or *doloire* with the first circle of the roller. Three or four *doloires* or turns, each of which covers about one-third of the preceding one, are to be made, and then the upper part of the arm is to be once surrounded with a plain circle of the bandage. This last circular application leaves between it and the cross previously made, a triangular equilateral space, technically named by writers *gera*

nis. The roller is now to be carried upwards in a spiral manner; its head is to be brought to the opposite armpit, and the application of the whole concludes with a few turns round the body. The bandage is to be fastened with pins at the place where it commences.

In applying the *spica inguinis*, the end of the roller is to be placed on the spine of the os ileum of the affected side. The bandage is then to be carried obliquely over the groin, and under the perinæum. Then it is to pass over the back of the thigh, and next forwards, so as to cross the part previously applied on the front of the groin. The application is continued by carrying the roller over the pubes, over the opposite os ileum, and next round the body above the buttocks. The bandage thus returns to the place where it began. Its application is completed by making a few turns like the preceding ones, and, lastly, a few circles round the body.

SPINA BIFIDA. (i. e. the Cloven Spine.) *Hydro-Rachitis.* A disease attended with an incomplete state of some of the vertebræ, and a fluid swelling, which is most commonly situated over the lower lumbar vertebræ, sometimes over the dorsal and cervical ones, and, in some instances, over the os sacrum. The same name has also been given to an analogous tumour, which sometimes occurs on children's heads, attended with an imperfect ossification of a part of the cranium. The malformation of the spine seems to consist in a deficiency of one or more of the spinous processes. Sometimes, indeed, these processes are wanting the whole length of the vertebral column, as was seen in the case reported by Fielitz.—(See *Richter's Chir. Bibl. b.* 9, *p.* 185.) Sometimes the tumour is composed of two distinct cysts, as happened in the case recorded by Mr. Brewerton (*Edin. Med. and Surg. Journ. vol.* 17); but this is uncommon.

The Arabians, who first treated of this disease, erroneously imputed the deficiency of one or more of the spinous processes to the tumour, while it is now well known that the incomplete state of the affected vertebræ is a congenital malformation, and that the swelling is only an effect. In fact, the tumour generally becomes larger and larger the longer it continues. The spina bifida may be regarded as an affliction only met with in children: few, very few, live to the adult age with this incurable affection. Warner, however, has related a case in which the patient lived till he was twenty.—(*Cases in Surgery, p.* 134, *edit.* 4.) I have also seen, under the care of Mr. C. Hutchison, a young woman, nineteen years of age, who had a spina bifida, which was of astonishing size, and situated at the lower part of the vertebral column. One curious circumstance in the case was, that the patient used to menstruate through a sore in the thigh. I conclude this is the same case as is described by Mr. Jukes (see *Med. and Phys. Journ. for Feb.* 1822), and who states the measurement of the swelling to have been thirty inches in its vertical line. The urine and feces used to pass involuntarily.

As I have remarked, the swelling is most frequently situated towards the lower part of the spinal canal, particularly at the place where the lumbar vertebræ join the sacrum. The fluid which it contains resembles serum, being somewhat more liquid than the white of egg, and, like the latter, frequently coagulable. It is in general limpid and colourless; but, occasionally, it is turbid and tinged with blood. On pressing the tumour, a fluctuation is very perceptible, and a preternatural space may also be felt existing between some of the spinous processes. The fluid is contained in a kind of cyst, which is composed of the continuation of the dura mater investing the spinal canal, and is for the most part closely adherent to the integuments.

According to Morgagni, spina bifida is mostly attended with hydrocephalus, and the enlargement of the head has been known to undergo a considerable diminution after the casual rupture of the tumour of the spine.—(*De Sed. et Caus. Morb. epist.* 7, *art.* 9. *Ephem. Cur. Nat. decad.* 3, *art.* 1, *decad.* 2, *art.* 2.) The fluid which was lodged in the lateral ventricles and third ventricle, passed into the fourth, through the aquæductus Sylvii, ruptured the calamus scriptorius, and thus passed into the spinal canal.

Spinæ bifidæ usually occur on the lower part of the spine; but they occasionally take place on the cervical vertebræ, where the tumours have the same characteristic marks as those near the sacrum. Many facts recorded by Ruysch, in his *Anatomical Observations* confirm the preceding account.

The present affliction is one of a most incurable nature; for, with the exception of one case mentioned by Morgagni (*De Sed. et Caus. Morb. epist.* 12, *art.* 9), a second, recorded by Keilmann (*Prodrom. Act. Havn. p.* 136), and two or three others more recently published by Sir Astley Cooper, there is not, I believe, in all the records of medicine or surgery, any case which either got well of itself, or was benefited by any mode of treatment. Opening the tumour either with caustics or cutting instruments, has generally only tended to hasten the fatal event of the disease. Death soon follows an operation of this kind, and sometimes instantly. Tulpius observes on this subject: *quam calamitatum si quidem reformides, chirurge, cave sis improvide aperias, quod tam facilè occidit hominem.*—(*Observ. Med.*)

But, whether the tumour be opened or not, still the disease is one of the most fatal to which children are exposed. When afflicted with it, they very seldom live till they are three years of age; but after lingering several months from their birth, suddenly die. It has been said, that children with spina bifida always have their legs in a paralytic state. However, this is not true; for one of the largest spina bifida I ever saw was under my friend Mr. Maul, of Southampton, and was unattended with any weakness of the legs. Indeed, the child was, to all appearance, as stout, healthy, and full of play as possible. The fatal event, however, took place after a time, as usual; and if my memory does not fail me, Mr. Maul noticed that a little before death, a remarkable subsidence of the swelling occurred, though it never burst externally. Still it is a fact, that many infants with spina bifida, have paralytic legs, and can neither retain their feces nor urine.

If we draw our own inferences from the cases and remarks offered by almost every writer on spina bifida, we must regard all attempts to cure the disorder, by making any kind of opening, as exceedingly perilous, if not positively fatal. It is to be observed, at the same time, that some practitioners have not altogether abandoned the idea of devising a mode of accomplishing a cure, at least in a few instances. Mr. B. Bell says, that if the tumour proceed from disease of the spinal marrow or its membranes, no means of cure will probably ever be discovered. But if the deficiency in the spinous processes of the vertebræ, with which the disease is always accompanied, be not an effect of the complaint, as was commonly imagined, and if the collection of fluid take place, from the want of resistance in the dura mater, in consequence of the imperfection of the bones, Mr. B. Bell questions whether it would not be proper to tie the base of the tumour with a ligature, not merely with a view of removing the swelling, but in order to resist the propulsion of the cyst farther outwards. Mr. Bell acknowledges that the event of this practice must be considered as very dubious; but expresses his wish to devise any plan that would afford even the least chance of success, in a case which must terminate in an unfavourable manner. Mr. Bell mentioned the design of putting the method to a trial on the first opportunity, and after the detachment of the swelling on the outside of the ligature, he intended to keep a soft compress on the part with a proper bandage. I do not know whether this gentleman ever put the above scheme in practice; but suppose not. It is properly objected to by the author of the article *Spina Bifida* in the *Encyclopédie Méthodique, part. Chir.*, because the disease is often attended with other mischief of the spinal marrow and brain, and the base of the swelling is almost always too large to admit of being tied at all, or not without hazard of dangerous consequences.

Richter has proposed the trial of two caustic issues at a little distance from the swelling; but I am not acquainted with any facts in favour of this practice.

Mr. Abernethy first suggested the trial of a gentle degree of pressure on the tumour from its commencement, with the view of producing absorption of the fluid, and preventing the distention of the unsupported dura mater. Were the fluid to continue to increase, notwithstanding such pressure, Mr. Abernethy thinks, that as death would be inevitable on the tumour bursting, it might be vindicable to let out the fluid by means of a puncture made with a finely-cutting instrument. The wound is to be immediately afterward closed

with sticking-plaster, and, if possible, healed. Another accumulation is then to be prevented, if practicable, with bandages and topical applications. Mr. Abernethy actually made the experiment of a puncture in one hopeless instance, in which, indeed, the swelling had previously just begun to burst. The puncture was repeated every fourth day for six weeks, during which time the child's health continued unaffected. The wounds were regularly healed; but the plaster having been rubbed off one of the punctures, the part ulcerated, the opening could not be healed, the discharge, from having been of an aqueous quality, became purulent, and death ensued. This case was also unfavourable for the trial of the method, as the integuments covering the tumour were diseased, and had no disposition to contract.

The annexed case, published by Sir Astley Cooper, will serve to show the benefit which may be derived from pressure.

"James Applebee, Baldwin-street, Old-street, was born on the 19th of May, 1807, and his mother, immediately after his birth, observed a round and transparent tumour on the loins, of the size of a large walnut. On the 22d of June, 1807, the child was brought to my house, and I found that, although it had spina bifida, the head was not unusually large; and the motion of its legs were perfect; and its stools and urine were discharged naturally. I applied a roller around the child's waist, so as to compress the tumour, being induced to do so from considering it a species of hernia, and that the deficiency of the spine might be compensated for by external pressure. The pressure made by the roller, had no unpleasant influence on its voluntary powers; its stools and urine continued to be properly discharged; but the mother thought that the child was occasionally convulsed. At the end of a week, a piece of plaster of Paris somewhat hollowed, and that hollow partly filled with a piece of loose lint, was placed upon the surface of the tumour; a strap of adhesive plaster was applied to prevent its changing its situation; and a roller was carried around the waist to bind the plaster of Paris firmly upon the back, and to compress the tumour as much as the child could bear. This treatment was continued until the month of October, during which time the tumour was examined about three times a week, and the mother reported that the child was occasionally convulsed. When the child was five months old a truss was applied, similar in form to that which I sometimes use for umbilical hernia in children, and this has been continued ever since. At the age of fifteen months, it began to make use of its limbs; it could crawl along a passage and up two pair of stairs. At eighteen months, by some accident, the truss slipped from the tumour, which had become of the size of a small orange, and the mother observed, when it was reduced, that the child appeared in some degree dull; and this was always the case, if the truss was left off for a few minutes, and then re-applied. At fifteen months, he began to talk; and at two years of age, he could walk alone. He now goes to school, runs, jumps, and plays about as other children. His powers of mind do not appear to differ from those of other children. His memory is retentive, and he learns with facility. He had the measles and small-pox in the first year, and the hooping-cough at three years. His head previously and subsequently to the bones closing, has preserved a due proportion to other parts of the body. The tumour is kept by the truss entirely within the channel of the spine: but when the truss is removed, it soon becomes of the size of half a small orange. It is therefore necessary that the use of the truss should be continued. When the truss is removed, the finger can be readily pressed through the tumour into the channel of the spine."—(*Med. Chir. Trans. vol.* 2, *p.* 323, *&c.*)

The next case, also published by Sir Astley Cooper, will prove that spina bifida may sometimes be treated on another plan, so as to accomplish a permanent cure.

"January 21st, 1809, Mrs. Little, of No. 27, Limehouse Causeway, brought to my house her son, aged ten weeks, who was the subject of spina bifida. The tumour was situated on the loins: it was soft, elastic, and transparent, and its size about as large as a billiard ball when cut in half; his legs were perfectly sensible, and his urine and feces were under the power of the will, &c. Having endeavoured to push the water contained in the tumour into the channel of the spine, and finding that, if the whole was returned, the pressure would be too great upon the brain; I thought it a fair opportunity of trying what would be the effect of evacuating the swelling by means of a very fine-pointed instrument, and by subsequent pressure to bring it into the state of the spina bifida in Applebee's child. I therefore immediately punctured the tumour with a needle, and drew off about two ounces of water. On the 25th of January, finding the tumour as large as before it had been punctured, I opened it again, and in the same manner, and discharged about four ounces of fluid. The child cried when the fluid was evacuated, but not while it was passing off. On January 28th, the tumour was as large as at first: I opened it again, and discharged the fluid. A roller was applied over the tumour and around the abdomen. February 1st, it was again pricked, and two ounces of fluid discharged. On the 4th, three ounces of fluid were discharged. On the 9th, the same quantity of fluid was evacuated as on the 4th; but instead of its being perfectly clear as at first, it was now sanious, and it had been gradually becoming so in the three former operations. On the 13th, the same quantity of fluid was taken away; a flannel roller was applied over the tumour and around the abdomen; a piece of pasteboard was placed upon the flannel roller over the tumour, and another roller over the pasteboard to confine it. On the 17th, three ounces of fluid, of a more limpid kind, were discharged; the pasteboard was again applied. On the 26th, the surface of the tumour inflamed: the fluid, not more than half its former quantity, was mixed with coagulable lymph, and the child suffering considerable constitutional irritation, was ordered calomel and scammony, and the rollers were discontinued. On the 27th, the tumour was not more than a quarter of its former size; it felt solid; the integuments were thickened, and it had all the appearance of having undergone the adhesive inflammation. On the 28th, it was still more reduced in size, and felt solid. March 8th, the swelling was very much lessened; the skin over it thickened and wrinkled; a roller was again had recourse to; a card was put over the tumour, and a second roller was applied. March 11th, the tumour was much reduced; the skin covering it was a little ulcerated. On the 15th, it was flat, but still a little ulcerated. On the 27th, the effused congulable lymph was considerably reduced in quantity, and of a very firm consistence. On the 2d of May, nothing more than a loose pendulous bag of skin remained, and the child appearing to be perfectly well, the bandage was soon left off. On December the 18th, the child was attacked with the small-pox, and went well through the disease. The skin now hangs flaccid from the basis of the sacrum; its centre is drawn to the spine, to which it is united, and thus the appearance of a navel is produced in the tumour by retraction of the skin. The pricks of the needles are very obvious, forming slight indentations."—(See *Med. Chir. Trans. vol.* 2, *p.* 326—329.)

At the time when Sir A. Cooper transmitted this case to the Medical and Chirurgical Society, it had been under his observation two years and a half.

The first of the preceding observations exemplifies the palliative treatment, adopted by the latter gentleman, and consisting of the application of pressure in the manner of a truss for hernia; the second shows the radical mode of cure by puncturing the swelling from time to time with a needle, and exciting the adhesive inflammation, which, with the assistance of pressure, stops the disease altogether, that is to say, in such examples as admit of cure.

Children are sometimes born with tumours analogous to spina bifida, but situated on the head. There is a deficiency of bon at some part of the skull, and through the opening a sac, composed of the dura mater, protrudes covered only by the integuments. Mr. Earle lately met with such a swelling situated upon the occiput of a femal infant. The plan of repeatedly making small punctures with a common needle, discharging the fluid, healing up the punctures and applying pressure, was tried, and followed up for some time, without the occurrence of any unpleasant symptoms. Even punctures were sometimes made with an ordinary lancet; yet the child suffered no harm from the operation, and some hopes of a cure were indulged. At length, however, ulceration of the swelling took place, the child became indisposed, and rapidly sunk.—(See *Med. Chir. Trans. vol.* 7, *p.* 427.) Consult *Ruysch*

SPINA VENTOSA. The Arabian writers first employed this term to express a disease in which matter formed in the interior of a bone, and afterward made its way outwards beneath the skin. Until the matter had escaped from within the bone, these authors describe the pain as being incessant and intolerable; but that after the pus had made its way outwards by fistulous openings, the patient's suffering underwent a considerable diminution. The matter sometimes insinuated itself, from the interior of the bone, into the cellular substance, so as to render it soft and flabby, though not always attended with any change of colour in the skin. The swelling had some of the appearance of emphysema. To express this state, the Arabians added the term *ventosa* to that of *spina*, which was employed, before their time, to express the nature of the pain attendant on the disease.—(See an account of this subject in the *Encyclopédie Méthodique, part. Chir. art. Spina Ventosa.*)

The term *spina ventosa* has, since the time of the Arabian writers, been used by many to signify the disease named *white swelling*, and they might also mean by it a similar affection, though the contrary may be inferred from their account of the matter passing from the interior of the bone under the integuments, a thing, which, I believe, never yet happened in any case of white swelling. Another, and perhaps a decisive argument, against the original signification of the word being the same as that of white swelling is, that it was not restricted to diseases of the joints and heads of the bones; but was also applied to abscesses which commenced in the cavities of the middle portions of the long bones, where, I need hardly observe, white swellings never make their attack.

For these reasons, many respectable authors have implied by the term *spina ventosa*, an abscess in the interior of the bone.—(See, on this subject, *Latta's System of Surgery, vol.* 1, *p.* 165.) Cases of this latter kind, I know, are infinitely rare, compared with that common disorder the white swelling: and I am also certain, from the descriptions given by some authors, that their cases of spina ventosa were in reality instances of necrosis. But that abscesses do occur and begin in the interior of the bones, more particularly of those of young persons, I have no doubt myself, both from two or three cases which I remember having seen in St. Bartholomew's Hospital, and from some cases recorded by the most authentic writers. I can hardly conceive that suppuration can take place to any extent within a long bone without being followed by necrosis.

Dr. Cumin, however, whose ingenious arrangement of diseases of bones has just made its appearance, saw a case in which, though matter had formed within one of the bones of a diseased finger, and was in a state of decay, it was certainly not affected with necrosis; "for interstitial absorption seemed to be going on in it to the last, and no line of separation could be detected between the diseased parts and the healthy articulating extremities."—(See *Edin. Med. and Surg. Journ. No.* 82.)

J. L. Petit relates, that a man with a tumour on the middle of the tibia, who had been treated by him as a venereal patient, found, a fortnight afterward, that the pains, which had never ceased, now began to grow more violent. The patient was feverish, his legs became red and even painful externally. An incision was made in the situation of the tumour, with a view of letting out the matter which was suspected to be the occasion of the bad symptoms, and to have insinuated itself under the periosteum. The incision was of no service, and two days afterward the trepan was applied, by which means a large quantity of matter was let out. The medullary part of the bone seemed quite annihilated, and the cavity almost empty. Petit made three other perforations with the trepan, and cut away the intervening pieces of bone. The actual cautery was also used several times to destroy the caries, and the patient at length got well.—(*Traité des Maladies des Os, de J. L. Petit.*) If any one doubt that abscesses form in the middle of the long bones, I must request him to consult Mr. Hey's *Practical Obs. in Surgery, p.* 22, where he may peruse two very interesting cases illustrative of what Mr. Hey calls *Abscess in the Tibia with Caries.*

It must be confessed, however, that these were only cases of necrosis, for which affection the term caries is too often inaccurately used. Indeed, it would appear from the observations of Dr. Macartney, that a very small suppuration in the medulla is accompanied with the beginning of those changes of the periosteum which attend necrosis.—(See *Necrosis.*)

SPIRITUS AMMONIÆ COMPOSITUS. Besides the well-known uses of this medicine internally exhibited, its vapours are occasionally applied to the eye in some cases of chronic ophthalmy. Scarpa recommends a remedy of a similar nature.

SPLINTS. Long thin pieces of wood or tin, or strong pasteboard, employed for preventing the ends of broken bones from moving so as to interrupt the process by which fractures unite. They are sometimes used in other cases, for the purpose of keeping the joints motionless, particularly in some kinds of dislocations, wounds, &c.

In simple fractures of the arm, forearm, or even of the thigh or leg in young infants, it matters not whether the splints be made of wood, pasteboard, or tin. In this country, surgeons usually keep sets of splints made expressly for the leg. These are of different sizes, excavated and shaped to the part, and furnished below with apertures for the projecting malleoli. When the limb is laid upon its outside, the foot is also usually supported and kept steady by the under splint extending some distance towards the toes. Very excellent splints for the legs of young children are made of strong pasteboard, accommodated in shape to the contour of the limb. Splints for the thigh, arm, and forearm, whether made of tin or wood, should always be slightly concave on the side, which is to be applied to the broken limb. They should likewise be made as thin and light as is consistent with the necessary degrees of strength for preventing the broken bone from bending. The sets of splints which are used for fractured legs and thighs in England, are frequently furnished with straps which have a great many small perforations in them at stated distances, and can thus be easily fastened by means of little pegs for the purpose. Tapes are also sometimes employed; but they often get loose, and cannot be depended upon so well as leather straps. Pasteboard, as a material for splints, has one advantage, viz. when wet it becomes soft, and admits of being accurately applied to every point of the surface of the limb; consequently, as soon as it dries and recovers its firmness again, it retains the exact shape of the part, and makes every where equal pressure on it, without incommoding the patient. Pasteboard, however, is hardly strong and durable enough for many fractures; nor will it answer when there is a discharge, nor when the surgeon wishes to employ any fluid applications. But it is generally allowed, that no substance is better calculated for supporting the fractured lower jaw; for it is perfectly strong enough for this particular case, and if wet before being applied, it forms, when dry, a solid covering most accurately corresponding to the shape of the jaw.

Whatever may be the substance of which splints are made, they ought always to be at least as long as the fractured bone; and if the situation of the limb

will allow, they ought, says Boyer, to extend its whole length. "For instance (says he), for simple fractures of the thighs of very young children, the pasteboard splints which I employ, reach from the upper part of the thigh, to the lower part of the leg. Generally speaking, the longer splints are, the better they fix the limb, and keep the fracture steady."—(*Boyer, Traité des Mal. Chir. t.* 3, *p.* 50.)

The number of splints must depend upon their breadth and the thickness of the limb. For the forearm two are sufficient; for the upper arm and thigh four are often used; and for the leg two, and sometimes three.

In cases of fractured thighs, when the straight position is preferred, the external splint should extend from the crista of the ileum to some little distance beyond the sole of the foot; while the inner one should reach from the upper and internal part of the thigh also beyond the sole of the foot. With respect to the anterior splint, it is indifferent whether it only reaches from the groin to the knee, or as far as the lower part of the leg.

The lateral splints for a broken leg ought to be sufficiently long to embrace the knee and confine the motions of the foot and ankle. When the straight posture is adopted, a splint is frequently laid along the front of the leg, from the patella to the lower part of the tibia. None, however, can ever be required under the limb, as there the bedding itself more conveniently affords the necessary degree of support.

Of all the different pieces of the apparatus for the treatment of fractures, the splints are by far the most important and essential. Without them, indeed, it would be in vain to attempt to keep the extremities of the fracture from being displaced.

As splints are generally composed of hard materials, the bad effects of their pressure upon the skin must always be counteracted by placing a sufficient quantity of tow, wool, or other soft substance, between them and the limb.

In order to understand, however, the principles which should guide the surgeon in the choice and application of splints, many remarks offered in the article *Fracture* must be consulted.

SPONGIA PRÆPARATA. (*Prepared Sponge; Sponge-tent.*) Formed by dipping pieces of sponge in hot melted emplastrum ceræ compositum, and pressing them between two iron plates. As soon as cold, the substance thus formed may be cut into pieces of any shape. It was formerly much used for dilating small openings, for which it was well adapted, as when the wax melted, the elasticity of the sponge made it expand and distend the opening. However, the best modern surgeons seldom employ it.

SPONGIA USTA. (*Burnt Sponge.*) This medicine, which the preparations of iodine are likely to supersede, was often given in the form of lozenges in cases of bronchocele, in which particular instances much efficacy was imputed to allowing the lozenges to dissolve gradually under the tongue. Burnt sponge has also been exhibited in many scrofulous diseases, and in chronic enlargements of the prostate gland. The dose is from a scruple to a drachm.

STAFF. An instrument of considerable importance in the operation of lithotomy, being in fact the director for the gorget or knife. It is made of steel, and its handle is generally rough, in order that it may be more securely held. As it is intended to be introduced through the urethra, its shape ought to be principally determined by the natural course of that passage. The English generally employ a staff, the curvature of which forms the segment of a larger circle than that described by the curvature of a staff used by the French practitioners.—(See *Roux, Voyage fait à Londres en* 1814, *ou Parallèle de la Chirurgie Angloise, &c. p.* 319.) In other words, the French staff turns more upwards than ours, as it approaches and enters the bladder. There may be some advantage in this construction, inasmuch as it tends to make the gorget enter in the direction of the long axis of the bladder; yet a great deal more seems to me to depend upon the position in which the staff is held, than upon its shape. Lithotomists should always employ as large a staff as can be easily introduced, because the operation will thereby be facilitated. The groove, the most important part of the staff, is of course situated upon the convexity of the curved part of the instrument, or upon that portion which, when introduced, lies in the membranous part of the urethra, prostate gland, and the bladder. It should always be made very broad and deep, as recommended by Langenbeck and Martineau.—(See *Lithotomy.*) The termination of the groove, at the end of the instrument, should be closed so as to stop the farther entrance of the gorget, and prevent the beak of the latter instrument from doing mischief. English surgeons have been justly censured by Desault and Sabatier, for neglecting this essential caution; for certainly the most fatal injury may be done by the gorget slipping beyond the end of the staff.—(See *Lithotomy.*) For my own part, if I can more sure of any one thing in surgery than another, it is this, that the beak of a gorget in the bladder ought never to pass out of or beyond the groove on the staff.

STAPHYLOMA (from σταφυλὴ, a grape, from its being thought to resemble a grape), is that disease of the eyeball, in which the cornea loses its natural transparency, rises above the level of the eye, and even projects beyond the eyelids, in the form of an elongated, whitish, or pearl-coloured tumour, which is sometimes smooth, sometimes uneven, and, according to Scarpa, attended with total loss of sight. However, staphyloma is either *partial* or *total;* that is to say, it affects only a part or the whole of the cornea; and in the first case, if there be not too much additional injury of the eye, a degree of vision may yet be left, and even admit of farther improvement. The circumstance of Scarpa's observations applying only to cases in which the eyesight is already destroyed, accounts for some important differences between him and other writers, who, in the practice which they advise, refer to the *partial* staphyloma, and cases in which the sight is not quite annihilated. Scarpa does not mention adhesion of the iris to the diseased cornea, as a part of the definition of staphyloma; a point in which he differs both from Richter and Beer.—(*Lehre von den Augenkr. b.* 2, *p.* 69.) However, Scarpa may be correct; for though, as Mr. Wardrop remarks, "the internal surface of the cornea adheres to the iris in *almost* every case of staphyloma" (*Essays on the Morbid Anat. of the Eye, vol.* 1, *p.* 101), yet as it does not invariably do so, the circumstance forms no essential part of the nature of the disease. In some instances, Mr. Wardrop has seen the opacity confined to one half of the cornea, generally the lower one.—(*Vol. cit. p.* 100.)

Scarpa observes, that infants are often attacked by this disease soon after their birth, and mostly in consequence of purulent ophthalmy. It is also produced by the small-pox, yet never during its eruption, nor during the stage of suppuration, but when the pustules dry, and even after the detachment of the variolous scabs.

In a great number of subjects, says Scarpa, when staphyloma has attained a certain elevation above the cornea, it becomes stationary, or only increases in due proportion to the rest of the eye. In other instances, the small tumour of the cornea enlarges in all its dimensions, and in such a disproportion to the rest of the eye, that at length it protrudes considerably between the eyelids, to the great molestation and deformity of the patient.

This disease is justly considered as one of the most serious to which the eyeball is subject; for to the total and irremediable loss of sight that it occasions, are added all the evils which necessarily result from the bulk and protuberance of the staphyloma. In such circumstances, the continual exposure of the eyeball to the contact of the air and particles of matter suspended in it; the friction of the eyelashes; the incessant flux of tears down the subjacent cheek; render the eye painful and inflamed; the sound one is affected by sympathy, and the diseased one at length ulcerates, together with the lower eyelid and cheek on which it presses.

According to Richter (*Obs. Chir. fasc.* 2), staphyloma is generally formed without the swelling of the cornea being preceded by any of those morbific dispositions which are usually considered capable of weakening the texture and elasticity of the cornea; which, in fact, acquires a much greater thickness than what it has in its natural state, and consequently staphyloma, far from being concave within, is every where compact and solid; though it ought to be quite the contrary, if the tumour were occasioned, as Beer yet appears to believe, by an immoderate distention operating on the cornea from within outwards with absorption of its natural texture.

Scarpa thinks that Richter has generalized his doctrine too much, by not drawing any line of distinction

between the staphyloma of recent occurrence in infants and that of adult subjects, in whom the disease has acquired so large a volume, as to protrude considerably beyond the eyelids. He agrees with Richter, that the recent staphyloma in infants is quite compact and solid, on account of the augmented thickness of the cornea; but he is convinced by repeated observation, that, in this very same staphyloma, originally quite solid and compact, the cornea becomes thinner, or at all events is not thicker than natural after the disease has existed a series of years in adult subjects, and in whom the swelling of the cornea has attained such a size as to protrude between the eyelids. The tumour, he observes, is not solid throughout, except in regard to its containing, in its amplified state, the iris, the crystalline, and very often, also, a portion of the vitreous humour.

The cornea of infants in its natural state is at least twice as thick and pulpy as that of adults, and consequently the anterior chamber of the aqueous humour in the former is comparatively so contracted to what it is in the latter, that in infants at the breast the cornea may be considered as in contact with the iris.

To such qualities of the cornea, in children of tender years, and to the natural narrowness of the anterior chamber of the aqueous humour, Scarpa imputes the cause why ophthalmies in infants so often produce opacity and thickening of this membrane. The cornea swells, becomes preternaturally thickened, and is very soon converted into a pointed, whitish, or pearl-coloured tumour, without any cavity internally, and either in perfect contact with, or adherent to, the iris. In the course of years, however, this disease undergoes new modifications. For, as the whole eye enlarges with age, the iris and crystalline lens, from causes not sufficiently understood, abandon their natural situation, and are propelled forwards, nearer and nearer to the cornea, which they in time distend in all its dimensions, so as to make it project beyond the eyelids, at the same time rendering it thinner in a ratio to its bulk and magnitude. Scarpa has never met with a voluminous staphyloma, projecting beyond the eyelids in adult persons, which had not originally made its first appearance in infancy; and he has invariably found that the thickness and density of the cornea, both in the living and dead bodies of those who have been affected with this disease, were in an inverse ratio to the eye. In inveterate cases of staphyloma, forming a large protuberance beyond the eyelids, the iris may here and there be clearly discerned through the diseased cornea, and if it be not equally manifest at all points of the tumour, it is because the conjunctiva externally spread over the cornea forms, in conjunction with its varicose vessels, on the surface of the tumour a stratum of matter not every where equally dense and opaque. This dense stratum of the conjunctiva spread over the cornea easily causes deception in a staphyloma of considerable bulk. The more the tumour increases, the more the substance of the cornea seems to become dense and thickened; while, in reality, the contrary happens; for the augmentation in the density of the layer of the conjunctiva, covering the cornea, only partly supplies the diminution in the thickness of the latter membrane. In staphyloma, as Mr. Wardrop observes, "the pupil is hid according to the situation and degree of the opacity of the cornea; but, in most cases, it is altogether obliterated, and even in those where a transparent portion of the cornea is opposite to it, the vision is much impaired; for, as *the eye has lost its form as an optical instrument, the change in its refractive power must render objects very indistinct.*"—(*Morb. Anat. of the Eye, vol.* 1, *p.* 101.)

The sclerotica is also subject to staphyloma, that is, to a partial distention and prominence of its anterior hemisphere in the white of the eye. Scarpa never met with any tumour or prominence on the front surface of the sclerotica, corresponding to the white of the eye; but in the dead subject he has met with two examples of staphyloma in the posterior hemisphere of the sclerotica. According to Mr. Travers, in the spheroidal staphyloma of the cornea, the sclerotica sometimes yields so much as greatly to increase the deformity. "This happens in hydropic and other degenerations of the humours. It also frequently becomes attenuated or bulged, near its junction with the cornea, in the amaurosis which follows inflammation of the choroid. This protrusion, larger or smaller, is sometimes circumscribed, and in other instances diffused over a large portion of the ball. It is often seen encircling the cornea, and presenting a sacculated or pouched appearance. It has a bluish-gray tint," &c.—(*Synopsis of the Diseases of the Eye, p.* 130.)

When, in the staphyloma of the cornea, this part is affected with irremediable opacity, Scarpa thinks that if the disease be recent, and in a child, the only object must be to hinder the increase of the swelling of the cornea, the organization of which is already destroyed. The tumour must be levelled and flattened as much as possible; and when the swelling of the cornea is inveterate, very large, and prominent beyond the eyelids, it is to be diminished by surgical means, so that it may return within the orbit, sufficiently to permit the deformity of the face to be amended by the application of an artificial eye.

In cases of recent staphyloma, Richter used to make at the bottom of the tumour of the cornea an artificial ulcer, by repeatedly applying the argentum nitratum, or the oxygenated muriate of antimony (butter of antimony), and to keep the little sore open by the continued use of the same caustic, with the view of effecting a diminution of the swelling of the cornea. In this way he frequently succeeded in lessening staphyloma, and in one particular case, he even restored the transparency of the cornea. *Ter repetitâ operatione, quarto scilicet, septimo et decimo die, ne vestigium quidem morbi die decimo-quarto superabat. Obs. Chir. fasciculus* 2. In this plan, Mr. Guthrie conceives that Richter evidently meant that the small ulcer made with the caustic should penetrate the cornea; and that from not comprehending this particular, Scarpa's trials of the method were unsuccessful.—(*Operative Surgery of the Eye, p.* 175.) It appears, however, that Richter himself never intended nor attempted any thing more, than what Scarpa did afterward; for he expressly cautions the surgeon not to let the caustic penetrate through the cornea. This meaning, indeed, admits of no doubt: in his chapter on staphyloma, he refers for the description of the method to his observations on leucoma (*Anfangsgr. &c. b.* 3, *p.* 138, 139), where it is distinctly stated, "*immer muss man wohl darauf merken dass das geschwür nich zu tief in die hornhaut eindringt, und dieselbe ganz und gar durchfrisst.*" Richter does not claim the proposal as one originally made by himself, but mentions it as a suggestion made by Günz.—(*Diss. de Staphylomate.*)

Though Scarpa frequently attempted to cure the recent staphyloma of infants by the above method, he never met with such success as could be at all compared with Richter's, either in restoring the transparency of the cornea, or accomplishing a diminution of the volume of the staphyloma. Having formed with the argentum nitratum a small ulcer at the bottom of the cornea, and kept the sore open thirty days and more, he failed in obtaining any benefit, in respect to the diminution, much less the opacity, of the cornea, in three infants, one a year and a half old, and the two others somewhat more than three, all which subjects had been recently attacked by staphyloma in one eye, in consequence of the small-pox. A violent chemosis, in a very short time, produced a staphyloma in the eye of a child five years old. Scarpa made an ulcer at the bottom of the cornea, into the unorganized swollen substance of which he introduced, for a little depth, the flat part of a lancet. The sore was kept open for five weeks, with a solution of the argentum nitratum, and the staphyloma became somewhat flatter, so as to lose the acute prominence in its centre; but the cornea continued, as before, every where opaque. Though Scarpa employed the same method in two other subjects, of about the same age and in the same circumstances; though he kept the ulcer open fifty days; he was never able to effect any depression or diminution of the staphyloma; and, consequently, the pointed, pearl-coloured, projecting part of the tumour continued in the same state as it was before. The conical shape which the cornea assumes in this disease, he observes, is a characteristic symptom, by which a staphyloma may be distinguished from a leucoma, with total opacity of the cornea.

If, also, in the course of farther trials, partial benefit be found to accrue from this plan, adopted not for the purpose of re-establishing the transparency of the cornea, but for that of merely checking and diminishing the recent staphyloma in infants, still Scarpa is of

opinion, that no one will be easily persuaded that the same treatment can ever prove of the least service in diminishing the size of the large, inveterate staphyloma in adults; in other words, of that which projects beyond the eyelids and rests on the cheek. Under these circumstances, he believes that there is no effectual means of restraining the progress of the complaint, and removing the deformity, but cutting away the staphyloma.

Mr. Guthrie considers Scarpa's application of Richter's method to young subjects erroneous, because the thickness of the cornea in them prevents the caustic from quickly penetrating the anterior chamber, and considerable inflammation is brought on.—(*Operative Surgery of the Eye*, p. 175.) It is to be recollected, however, that Scarpa, when he tried Richter's plan, never meant the caustic to penetrate the anterior chamber, but merely to form and keep up a sort of issue, the exact principle of treatment which Richter himself intended.

Celsus describes two modes of cure; viz. that with a ligature, and the removal of a portion of the conical most-projecting part of the diseased cornea.—(*Lib.* 9, *cap.* 7.)

Though, says Scarpa, the first plan, or that of the ligature, is at present abandoned, the majority of surgeons still persevere in passing a needle and ligature through the lower part of the staphyloma, not for the purpose of tying or constricting the tumour, it is true, but of making a noose, in order to fix the eye conveniently, when the staphyloma is to be cut off in a circular manner. This use of a needle and ligature, which, I observe, is sanctioned by Mr. Travers (*Synopsis, &c.* p. 285), is strongly disapproved of by Scarpa.

With regard to the second method of removing the staphyloma, or that of excision, Scarpa thinks that sufficient attention has not been paid to the directions of Celsus, that this operation should be done in the centre or conical point of the tumour, and that as much of this part of the staphyloma ought to be cut away as will equal a lentil in size: *In summâ parte ejus ad lenticulæ magnitudinem excindere.* Scarpa remarks, that the great importance of this precept can be duly appreciated only by those who have often had occasion to compare the advantages of Celsus's doctrine, with the serious inconveniences which result from the practice of cutting away the staphyloma circularly at its base; and with the evils produced by a semicircular section, comprehending the sclerotica, in Woolhouse's manner, always followed by acute inflammation of the eyeball and eyelids, violent pains in the head, restlessness, spasms, copious and sometimes gangrenous suppurations of the eye and eyelids.

The patient being seated, Scarpa directs an assistant to support his head properly; then taking in his hand a knife, similar to what is used in the extraction of the cataract, he passes the instrument completely across the staphyloma, at the distance of one line and a half, or two lines, from the centre or apex of the tumour, from the external towards the internal angle of the eye, and, by passing the knife forwards in the same direction, just as is done in the extraction of the cataract, he makes a semicircular incision downwards, in the most prominent part of the tumour. Having done this, he takes hold of the segment of the staphyloma with the forceps, and turning the edge of the knife upwards, he completes the circular recision of the apex of the tumour, in such a way that the detached portion is one, two, three, or four lines in diameter, according to the size of the staphyloma. As a portion of the iris adhering to the cornea from the very commencement of the disease is commonly included in this section of the pointed part of the tumour, no sooner is the circular division of the apex of the staphyloma made, than the crystalline, or its nucleus, issues from the eye, followed by a portion of the vitreous humour. In consequence of this evacuation, the eyeball is often so diminished, that it can be covered by the eyelids, to which Scarpa immediately applies a pledget of dry lint, supported by a retentive bandage.

When the eye and eyelids begin to be painful, inflame, and swell, as they generally do on the fourth day, the eye is to be covered with a bread and milk poultice. When things proceed in a regular manner, the swelling of the eyelids subsides about the seventh or ninth day, and purulent matter is seen on the poultice, blended with the vitreous humour. The matter afterward becomes thick and whitish, the patient feels great relief, and the eyeball shrinks and sinks into the orbit.

At this period, on gently separating the eyelids, the conjunctiva is found swelled, and reddish, and the margin of the wound seems like a whitish circle. This is usually detached on the twelfth or fourteenth day after the operation, when the edge of the surface from which the staphyloma was cut becomes red, contracts, and daily diminishes, so that at last the wound is entirely closed. There only remains in the centre of the cornea, for a few days, a small fleshy prominence, resembling a little reddish papilla, which, after being touched a few times with the argentum nitratum, contracts and heals.

So far, says Scarpa, are alarming symptoms from following this operation, that in a great number of cases the surgeon is even obliged, several days after ward, to stimulate the eye on which it has been performed, in order to make it inflame, partly by leaving it a long while uncovered and exposed to the air, partly by enlarging the circular recision made in the centre of the staphyloma, of which another circular portion half a line broad is removed, in order to facilitate the more abundant discharge of the humours, and the ingress of air into the cavities of the eye which are so backward to inflame. As soon as inflammation has invaded the interior of the eye, and suppuration has taken place, the rest of the cure regularly follows under the use of topical emollients, and is soon completed with all possible mildness.

It should be particularly recollected, that Scarpa means the foregoing practice for inveterate cases of staphyloma, where the eyesight is totally lost, and the projection of the diseased cornea produces serious annoyance. Under other circumstances it is not admissible. Among others, Dr. Vetch particularly objects to the removal of the apex of the tumour, as destructive of all chance of the recovery of a degree of vision; a consideration, however, which would not exist in the hopeless cases spoken of by Scarpa. Dr. Vetch also disapproves of letting out the aqueous humour in cases of staphyloma, as an endless operation from which no permanent effect takes place, the humour collecting again in a few hours; a sentiment which is likewise expressed by Mr. Travers.—(See *Vetch on the Diseases of the Eye*, p. 63; *and B. Travers, Synopsis, &c.* p. 286.) For the purpose of accomplishing the gradual diminution of the tumour, and *bringing the eye into a state in which an artificial pupil may be made*, Dr. Vetch has employed caustic (the method commended both by Richter and Beer), and the introduction of a seton through the tumour. Beer confirms the statement of Scarpa, concerning the impossibility of restoring the transparency of any part of the cornea affected with staphyloma. For the relief of a partial staphyloma, he prefers the cautious application of the oxygenated muriate of antimony, by means of the point of a camel-hair brush, while the eyelids are held asunder. The diseased part of the cornea is to be smeared with it until a small white superficial slough is formed, when every particle of the caustic must be immediately washed out of the eye with another larger camel-hair brush dipped in water or milk. The application is not to be repeated, until the subsequent inflammation has quite subsided, and the slough been thrown off. Beer condemns all escharotic salves, because their action extends to parts which should be left unirritated.—(*Lehre von den Augenkr. b.* 2, *p.* 74.) Mr. Guthrie regards the treatment with caustic as only applicable to cases in adult subjects, where the diseased cornea is thin, and the sclerotica nearly or quite healthy. The knife, he says, is requisite in young or old individuals, where the staphyloma is evidently thick and hard, and the front of the eye more or less varicose.—(*Operative Surgery of the Eye*, p. 174.) In this last condition, indicated by the bluish, leaden appearance of the sclerotica, which seems to be penetrated close to the cornea by many tortuous dark-red vessels, and accompanied in a more advanced stage by a bulging out of particular parts in the same situation, he says, "the anterior portion of the eye ought to be removed, and with it the vessels which are in a varicose state."—(*P.* 178.)

Wenzel and numerous other writers imply by staphyloma, a protrusion of a piece of the iris through a wound or ulcer of the eye.—(See *Iris, Prolapsus of.*)

STEATOMA. (From *στέαρ*, fat.) A wen or encysted tumour containing fat.—(See *Tumours, Encysted.*)

STELLA, or STELLATED BANDAGE. A bandage, so named because it makes a cross or star on the back. It is a roller applied in the form of the figure 8, so as to keep back the shoulders. It is often employed in cases of fractures and dislocations of the clavicle.

STRAMONIUM. A series of interesting experiments were detailed in illustration of the properties of stramonium in a Dissertation, which was read to the Medical Faculty of the University of Pennsylvania, on the 12th of May, 1797, by Dr. Samuel Cooper. The experiments No. 15 and 16 merit particular notice in this Dictionary, as being perhaps the earliest discovery of the effect of the local application of powerful narcotics in dilating the pupil. A drop of an infusion of the powder of stramonium was let fall into the left eye. In half an hour the pupil began to enlarge, and attained its greatest dimensions about twelve hours after the experiment, at which time it was viewed in a considerable light, and seemed thrice as large as the other. It continued dilated two days. In a strong light objects were seen more distinctly with the right eye; but in a weak light with the left. Some other gentlemen, however, on whom the experiment was tried, experienced no increased power of seeing in the dark. A drop of the expressed juice dropped into the eye of a cat, soon converted the whole of the coloured part of the eye into pupil.—(See *Caldwell's Medical Theses, p.* 173, 8*vo. Philadelphia*, 1805.) Stramonium then resembles belladonna and hyoscyamus in its action upon the iris. It has been exhibited internally in epilepsy, tic douloureux, and severe chronic pains, and used in poultices for dispersing indurations of the breast, and in ointments for allaying the pain of piles. The doses should at first be only gr. ss. of the extract twice a day, but they may be gradually increased to five grains.

[Stramonium has acquired great reputation in this country in the treatment of tic douloureux, and especially in rheumatism. In this latter disease it is used externally and internally, and is the basis of very many empirical anti-rheumatics. It is generally preferred in the form of tincture as an external application, though frequently used in the form of an unguent, prepared by boiling the fresh leaves in hog's lard.—*Reese.*]

STRICTURE. (From *stringo*, to bind.) A contracted state of some part of a tube or duct.—(See *Urethra, Strictures of; Œsophagus, &c., Rectum, &c.*) Stricture also means, in cases of strangulated hernia, the narrowest part of the opening or passage through which the bowels protrude.—(See *Hernia.*)

STRUMA. (From *struo*, to heap up.) Scrofula or Scrophula. The king's evil.—(See *Scrofula.*)

STYE. A little inflammatory tumour on the eyelid.—(See *Hordeolum.*)

SULPHURIC ACID. The strong sulphuric acid is used as a means of extricating from the nitrate of potash, or muriate of soda, certain gases for the purpose of purifying the air of sick rooms or infected places. A few practitioners have also sometimes employed it, blended with sixteen times its weight of lard, as a local application for the cure of scabies. One drachm of it, mixed with an ounce of lard, is sometimes rubbed upon diseased joints, and with considerable effect when the right cases are selected.—(See *Joints.*) As a caustic, this acid is not generally eligible, because it is difficult to limit its operation exactly to the parts which are intended to be destroyed. A few years ago, a proposal was made to apply it along the outside of the eyelid in cases of trichiasis, so as to produce a slough and subsequent ulcer, the cicatrization of which would draw out the inverted tarsus. Nay, it is alleged that the application sometimes produces an instantaneous amendment of the position of the eyelid. I have seen one example in which the experiment was tried; but whether it was owing to the acid not having been sufficiently applied or other causes, the method did not answer so well as the usual plan of removing a part of the integuments with a cutting instrument. Sulphuric acid has also been employed in the cure of ectropium.—(See *this word.*)

Diluted sulphuric acid is frequently employed as an ingredient in gargles. It is also commonly exhibited with a view of checking passive hemorrhages, and profuse nocturnal sweats in hectic fever. The dose is from ten to thirty drops.

This acid in the diluted form has been tried in venereal cases. According to Mr. Pearson, when a bad state of health prohibits the introduction of mercury, the case has not yet put on an unequivocal appearance, or dyspeptic symptoms, attended with profuse perspirations, harass the patient, it is a useful remedy, capable of giving a temporary check to the progress of the disease. He says, that he has often seen it arrest the progress of venereal ulcers of the tonsils, and make venereal eruptions fade and nearly disappear; but that these beneficial effects were never permanent. At the same time he acknowledges that the medicine will confer actual and durable benefit in ulcers of the penis, groin, and throat, sometimes remaining stationary after a mercurial course. He has likewise found this acid very efficient when mercury acts too violently upon the mouth.—(See *Pearson's Obs. on the Effects of various Articles in the Cure of Lues Venerea, p.* 189—191, *ed.* 2.)

In cases of poison by sulphuric acid, the most successful treatment consists in making the patient drink large quantities of water, in which calcined magnesia is suspended. Should this last medicine, however, not be at hand, soap blended with water is the best substitute. While these remedies are preparing, copious draughts of some mucilaginous beverage, milk, or even of common water, should be administered without delay; for the practitioner should ever be mindful, that so rapidly does sulphuric acid operate upon the texture of the parts with which it comes into contact, that all chance of saving the patient must depend upon the quickness with which the means to counteract the poison are applied. After the acid has been diluted and neutralized, local and general bleeding, emollient clysters, and mucilaginous drinks constitute the best remedies.—(*Orfila, Traité des Poisons &c. vol.* 1, *p* 434, *ed.* 2.)

SUPPRESSION OF URINE. See *Urine, Retention of.*

SUPPURATION. A process by which a peculiar fluid, termed *pus*, is formed in the substance, or from the surface of parts of the body. From observations in the article *Inflammation* it appears, that when this last affection is above a certain pitch, it sometimes terminates in suppuration.

When purulent matter accumulates in the part affected, it is termed an *abscess*, which is distinguished into several kinds—*acute, chronic, venereal, scrofulous, &c.*

It is observed by Professor Thomson, that the texture in which suppuration seems to be most readily produced by a certain degree of inflammation, is mucous membrane, whether this lines excretory ducts or canals, or covers the inner surfaces of the respiratory or urinary organs. In a few hours after an irritating cause has been applied to these surfaces, the physical and chemical qualities of the fluid which they secrete in their natural state are changed. From being a tough, viscid substance, not easily miscible with water, the mucus of the nose and bronchia becomes during an attack of inflammation, very readily miscible with water, of a yellowish-white colour, and fluid consistence. If in this state the secretion from these membranes be examined with the microscope, it will be found to contain small globules, similar to those which are seen in the blood; and these globules are found to increase in number in proportion to the degree and continuance of the inflammation. We have examples of the production of this pus, or at least of a puriform fluid, in the respiratory organs of persons affected with catarrh, and in the urinary organs of those who labour under gonorrhœa. In the progress of these diseases we

can generally trace the changes which take place by slow but sensible degrees in the nature of the secretion, from mucus to pus, and from pus back again to the state of mucus. This puriform discharge from mucous membranes in a state of inflammation may be kept up for months without these membranes appearing to undergo any other morbid changes than a slight degree of redness and swelling. A loss of substance or ulceration is found not to happen oftener than in one case out of ten examples of suppuration from mucous membranes.—(*On Inflammation*, *p.* 305, 306.)

The same well-informed writer afterward proceeds to explain, that suppuration may be readily produced in the skin or cutaneous texture, by whatever excites inflammation in that texture, and causes a separation of the cuticle. We have examples of this fact in blisters from cantharides, and in vesications of the cuticle from superficial burns. If the cuticle covering a recent blister or burn be removed, and the cutis exposed to the irritation of stimulating substances, pus will soon be discharged from the abraded surface. Suppuration can be kept up in cutaneous texture for an indefinite length of time, as we see done every day in the management of perpetual blisters. Ulceration is seldom observed in these cases, and, consequently, in cutaneous texture, loss of substance is by no means necessary for the production of pus.

If the cutis be divided, as in a wound, or a portion of it removed, as in the extirpation of tumours, and either the air or any other external body be permitted to remain in contact with the divided surfaces, the process of suppuration is speedily induced in the cellular texture subjacent to the skin. After the hemorrhage which takes place from the small vessels has ceased, an oozing of a fluid, at first resembling serum, occurs, which is gradually changed into pus. But in this case, as Dr. Thomson has correctly observed, the surface of the wound is previously covered with a layer of coagulable lymph, which is penetrated with blood-vessels, and gradually raised into the little red eminences termed granulations.

Appearances similar, though slighter in degree, says Dr. Thomson, are observed in cutaneous suppuration: giving probability to the opinion of Sir E. Home, that in inflammation a vascular surface is produced previously to the formation of pus in a cellular membrane, and perhaps also in cutaneous texture. Dr. Thomson is inclined to believe, however, that no new vascular surface is generated in the inflammation of mucous membrane. Thus we see, that in the formation of pus in mucous membrane, cutaneous texture, and exposed cellular substance, no ulceration, no breach of substance occurs; but that, on the contrary, in two of these textures, the cutaneous and cellular, there is an addition made to the parts by the exudation of coagulable lymph, which becomes organized.—(*Thomson*, *p.* 305—308.)

SYMPTOMS OF SUPPURATION.

When matter is fully formed in a tumour, there is a remission of all the symptoms. The throbbing pain, which was before frequent, now goes off, and the patient complains of a more dull, constant, heavy pain. A conical eminence, or *pointing*, as it is termed, takes place at some part of the tumour, generally near its middle. In this situation, a whitish or yellowish appearance is generally observable, instead of a deep red, which was previously apparent; and a fluctuation of a fluid underneath may be discovered, on a careful examination with the fingers. Sometimes, indeed, when an abscess is thickly covered with muscles and other parts, the fluctuation cannot be easily distinguished, though, from other concurring circumstances, hardly a doubt can be entertained of there being even a very considerable collection of matter. An œdematous swelling over the situation of deeply situated abscesses is a symptom which often occurs, and is well worthy the attention of every practical surgeon.

The discovery of the existence of deep abscesses is a circumstance of the highest importance in practice, and one which greatly involves the practitioner's reputation. In no part of surgery is experience in former similar cases of greater use to him than in the present: and however simple it may appear, yet nothing, it is certain, more readily distinguishes a man of observation and extensive practice, than his being able easily to detect collections of deep-seated matter. On the contrary, nothing so materially injures the character and professional credit of a surgeon, as his having in such cases given an inaccurate or unjust prognosis; for generally, in disorders of this kind, the nature and event of the case are at last clearly demonstrated to all concerned.

Together with the several local symptoms of the presence of pus already enumerated, may be mentioned the frequent shiverings to which patients are liable, especially on the first formation of acute abscesses. However, these rigors seldom occur so as to be distinctly observed, unless the collection of matter be considerable, or situated internally in some of the viscera.

"In the progress of the fever accompanying acute inflammation (says Professor Thomson), rigors or cold shiverings not unfrequently take place, which recur at irregular intervals, and are in general followed by a hot fit, and slight increase of the febrile symptoms. These rigors or cold shiverings in general indicate, when they occur in the progress of inflammatory diseases, that pus either is formed, or is about to be so. In inflammation succeeding to injuries of the head, these rigors are often the first constitutional symptoms which give alarm to the well-informed practitioner; for they are generally, though not always, an indication that inflammation has already made a dangerous if not fatal progress. These rigors also accompany the formation of pus in the viscera contained within the cavities of the chest and belly; and are often the first symptoms which inform the practitioner that his endeavours to procure resolution have not been successful."—(See *Thomson's Lectures on Inflammation*, *p.* 321.)

Rigors, as Mr. Hunter remarked, are more common at the commencement of spontaneous inflammations, than in inflammations from external injury. They seldom occur in the suppurations which follow operations.

According to Sir A. Cooper, when matter is formed upon the natural surfaces of the body which are connected with vital organs, much irritation and disturbance take place; but when matter is produced upon the surface of a wound in a part not important to life, or upon parts of little vital importance, then its formation is often unpreceded by irritative fever.—(See *Lectures*, *&c. vol.* 1, *p.* 113.)

The constitutional symptoms which attend the formation of pus in the progress of chronic suppurations, are generally comprehended under the name of hectic fever.—(See *Fevers*.)

The pain attending what Mr. Hunter termed *suppurative* inflammation, is increased at the time when the arteries are dilated, and this gives the sensation called throbbing, in which every one can count his own pulse, by merely paying attention to the inflamed part. Perhaps this last symptom is one of the best characteristics of this species of inflammation. When the inflammation is moving from the adhesive state to the suppurative, the pain is considerably increased; but when suppuration has taken place, the pain in some degree subsides.

The redness that took place in the adhesive stage is now increased, and is of a pale scarlet colour. The part which was firm, hard, and swelled in the previous stage of the inflammation, now becomes still more swelled, in consequence of the greater dilatation of the vessels, and the greater quantity of coagulating lymph thrown out.—(*Hunter*.)

THEORY OF SUPPURATION.

The dissolution of the living solids of an animal body into pus, and the power of this fluid to continue the dissolution, are opinions which are no longer entertained by any well-informed surgeons of the present day; and the use of such phrases as "*pus corrodes*," "*it is acrid*," &c. expressions which imply an erroneous way of thinking, is very properly almost entirely discontinued in the language of every sensible medical man. If these notions were true, no sore which discharges matter could be exempted from a continual dissolution. Such ideas probably arose from the circumstance of an abscess being a hollow cavity in the solids, and from the supposition that the whole of the original substance of that cavity was now the matter which was found in it. This was a very natural way of accounting for the formation of pus by

one entirely ignorant of the moving juices, the powers of the arteries, and what takes place in an abscess after it is opened. The knowledge of these three subjects, abstracted from the knowledge of the abscess before its being opened, should have led surgeons to account for the formation of pus from the blood by the powers of the arteries alone. According to the above erroneous principle, abscesses would continue to increase after being opened as fast as before. Upon the principle of the solids being dissolved into pus was founded the practice of bringing all indurated parts to suppuration, if possible, and not making an early opening. This was done for the purpose of giving time for the solids to melt down into pus; but it was apparently forgotten, that abscesses formed matter after they were opened, and, therefore, the parts stood the same chance of dissolution into pus as before. Blinded with the idea that the solids entered into the composition of pus, the partisans of this doctrine could never see pus flowing from any internal canal, as from the urethra, in cases of gonorrhœa, without supposing the existence of an ulcer in the passage. Such sentiments might be forgiven, before it was known that these surfaces could, and generally did, form pus, without a breach of the solids; but the continuance of this way of thinking now is not mere ignorance but stupidity. The formation of pints of matter in the cavities of the chest and abdomen, without any breach in the solids, could not have been overlooked by the most zealous advocates for the doctrine of dissolution. The moderns have been still more ridiculous; for, knowing that it was denied that the solids were ever dissolved into pus, and that there was not a single proof of it, they have been busy in producing what to them seemed a proof. They have been putting dead animal matter into abscesses, and finding that it was either wholly or in part dissolved, they therefore attributed the loss to its being turned into pus. This, however, was putting living and dead animal matter upon the same footing, which is a contradiction in itself; for if the result of this experiment were really what they supposed it to be, the idea of living parts being dissolved into pus must be abandoned, because living and dead animal matter can never be considered in the same light.

It might have been remarked, that even extraneous animal matter would lie in abscesses for a considerable time without being dissolved; and that in abscesses arising either from violence or from a species of erysipelatous inflammation, there were often sloughs of the cellular membrane, which sloughs would come away like wet tow, and, therefore, were not dissolved into pus.—(*Hunter.*)

It might also have been noticed, that in abscesses of tendinous parts, as about the ankle, a tendon often mortified and sloughed away, and that the sores would not heal till such sloughs were detached; but though this separation was sometimes not completed for several months, yet the sloughs were at last thrown off, and not converted into pus. Pieces of dead bone often lie soaking in matter for many months, without being changed into pus; and although bones so circumstanced may lose a considerable deal of their substance, a loss which some might impute to the dissolution of the bone into pus, yet such waste can be accounted for on the principle of absorption. The loss is always upon that surface where the continuity is broken off, and it is a part of the process by which the exfoliation of a dead piece of bone is accomplished. The formation of pus has been attributed to a kind of fermentation, in which both the solids and fluids were concerned. This doctrine is easily refuted by stating what happens in internal canals, which naturally secrete mucus, but frequently form pus without any loss of substance or any previous fermenting process. Were we to suppose a fermentation of the solids and fluids the immediate cause of the production of pus, whence could the solids come which enter into the composition of discharges from the urethra? for the whole penis could not afford matter enough to form the pus which is discharged in a common gonorrhœa. How also could the fermentation of the solids ever cease? for there is the same surface secreting its mucus whenever the formation of pus is discontinued. It may be asked, likewise, by what power the first particle of pus in an abscess or on a sore is formed, before there is any particle existing which is capable of dissolving the solids? An abscess may be stationary for months, and at last be absorbed: what becomes of the fermentation all the while the collection of matter continues stationary?

Extravasated blood has been supposed to be capable of being converted into pus. We find, however, that blood, when extravasated, either from violence or a rupture of a vessel, as in aneurism, never of itself becomes pus; nor was pus ever formed in these cases, without being preceded by inflammation. Both the blood and matter are also found together in the same cavity, under such circumstances. If the blood had coagulated, which it seldom does in cases of violence, it would be found still coagulated; and if it had not coagulated the pus would be bloody.—(*Hunter.*)

The modern theory of suppuration is, that the matter is separated from the blood by the secreting power of the vessels of the inflamed part, which acquire a new mode of action.

That pus is formed in the vessels from which it exudes, by an action of these vessels analogous to secretion, was, so far as I know (says Professor Thomson), first distinctly suggested by Dr. Simpson of St. Andrews, in his "*Dissertationes de Re Medica*," published in the year 1722. An opinion, similar to that of Dr. Simpson's, suggested itself, about the year 1756, to De Haen, from the consideration of what takes place in some cases of phthisis pulmonalis. This author observed, that pus was often expectorated for a great length of time, by patients affected with phthisis, in whom, after death, no mark of ulceration could be perceived, not even the place in which the pus had been formed. The hypothesis of pus being a secretion was afterward more fully considered by Dr. Morgan, of Philadelphia, in his inaugural thesis printed at Edinburgh in 1763, entitled "*Puopoioses, sive Tentamen Medicum de Puris Confectione.*" The belief that pus is a secretion, or formed at least by an action of the vessels analogous to secretion, was adopted by Mr. Hunter. Indeed, the merit of the original suggestion of this hypothesis has been ascribed to him, though improperly. Bruggman, professor of botany at Leyden, has maintained the same doctrine in an excellent thesis "*De Puogenia*," published in 1785; and it is that which is now very generally taught all over Europe.—(See *Thomson's Lectures on Inflammation*, p. 316, 317.) With respect to suppuration from exposed surfaces, however, it is more proper to say, that the vessels secrete a fluid which *becomes* pus; for Sir Everard Home has proved that this fluid has not the purulent appearance when first secreted, but acquires it while it remains on the inflamed surface, and does not acquire it the less readily when removed from that surface in a colourless state, provided its proper temperature be preserved, and it be kept exposed to the air, which promotes the change.

The opinion that suppuration is a process analogous to glandular secretion was at first hastily rejected by many, who were swayed by the fact that no pus is ever found blended with the blood in the circulating system. By this mode of reasoning, however, such thinkers must be led to deny the universally-received and undoubted doctrine that the bile is a secretion; and yet, it is well known that nothing like this fluid can be detected in an analysis of the blood, and, indeed, a very small quantity would be sufficient to tinge the whole mass of circulating blood with a yellow colour, the same as we see in cases of jaundice. No one would wish to defend the idea of there being either pus or bile actually in the circulation; but only the matter, or modifications of the matter, which, by the combinations, or whatever changes we may choose to term them, produced by the action of the secreting vessels, are converted into one of the particular fluids in question.

Violence done to parts is one of the great causes of suppuration; but simple violence does not always occasion it. The violence must be followed by something that prevents the cure in a more simple way, something that prevents the restoration of the structure, and the continuance of the animal functions of the part. The parts must be kept long enough in that state into which they were put by the violence. Or, what is somewhat similar to this, the violence must be attended with death in a part, as in many bruises, all mortifications, and all sloughs, in consequence of the application of caustic, which when

the dead parts separate, leave internal surfaces exposed. —(*Hunter.*)

As every injury, or effect of outward violence under the above circumstances, is more or less exposed to the surrounding air, the application of air to internal surfaces has been assigned as a cause of suppuration; but certainly the air has not the least effect on parts, circumstanced as above, for a stimulus would arise from a wound, were it even contained in a vacuum. In circumscribed abscesses, the air cannot possibly get to the parts, so as to have any share in making them suppurate.

In cases of emphysema, when the air is diffused over the whole body, no suppuration is the consequence, unless an exposure or imperfection of some internal surface should be made, for the purpose of allowing the air to escape. A stronger proof that it is not the admission of air which makes parts inflame is, that the cells in the soft parts of birds, and many of the cells and canals of their bones, communicating with the lungs, and always containing air, never inflame; but if these cells are exposed in an unnatural way, the stimulus of imperfection is given, these cavities then inflame, and their surfaces either form adhesions together, or produce pus.—(*Hunter.*)

When the interior of an abscess is examined, the cavity which contained the matter is observed to be lined with a smooth, membrane-like substance, which is of a whitish ash-colour, and has a strong resemblance to coagulating lymph. This membrane-like investment has been termed the *sac* or *cyst* of the abscess. It seems in general to adhere by a vascular union to the surrounding cellular membrane, which is itself likewise denser in texture, and more vascular than in the natural state (*Thomson's Lectures, p.* 310), its cells being closed by coagulating lymph, effused in consequence of that species of inflammation which Mr. Hunter termed the adhesive. Thus, by the formation of a cyst, and the effusion of coagulating lymph in the cellular substance around the abscess, the collection of matter is bounded and cannot become diffused, as it otherwise would do in the communicating cavities of the cellular membrane, like the water in œdema.

Something like this diffusion of pus seems to occur in erysipelas phlegmonoides. "But in this case (says Professor Thomson), the vitality of greater or less portions of the cellular substance is destroyed; the deadened portions are converted into dirty, whitish, ash-coloured sloughs; and it becomes extremely difficult to say whether any part of the pus contained in the deadened cellular membrane has been formed in the cells in which it is contained, or has been absorbed into these cells, after being separated from the parietes of the cavities containing the sloughs themselves."—(*Lectures, &c. p.* 310.)

There can be no doubt that, after an abscess has received a membranous lining or cyst, the secretion of pus is continued from the surface of the latter part entirely, as well as whatever degree of absorption of the same fluid happens to be going on. In fact, the cysts must be both secreting and absorbing surfaces. The circumstances which leave no doubt of this point, are the frequent, sudden, or gradual removal of very large manifest collections of matter; the continual changes occurring in the quantity and consistence of the pus; and the speedy filling of the cavity with purulent matter again after the first contents of the abscess have been discharged.

Another thing which is yet a subject of controversy is, whether suppuration ever happens unpreceded by inflammation? Professor Thomson, of Edinburgh, believes, that the affirmative opinion on this point was first suggested by De Haen, of Vienna; but he thinks that much of the difference of sentiment in this matter has proceeded from the vague "notions entertained with regard to the symptoms which necessarily characterize the state of inflammation, and also with regard to the properties by which pus is to be distinguished from other animal fluids. Accordingly, in almost all the examples which De Haen has adduced to prove the formation of pus, without the previous existence of inflammation, he has himself occasion to remark the exudation of coagulating lymph, and the existence of preternatural adhesions; phenomena, which we now know are produced by that state which Mr. Hunter has denominated adhesive inflammation." But De Haen uses the term inflammation to express that state which we denominate ulceration or ulcerative absorption; for in speaking of the cases of suppuration which he has adduced, he observes, that "in many of them no previous loss or consumption of substance could be perceived." An observation similar to this was made about the same time, or perhaps a little earlier, by Dr. W. Hunter, and an account given of it in the second vol. of the London Medical Observations and Inquiries.

"Mr. Hunter, though he endeavours to establish it as an invariable fact, that no suppuration takes place which is not preceded by inflammation, is of opinion, that collections of what he terms extraneous matter, something like pus, may form in various parts of the body without the previous existence of inflammation in the parts in which it is formed; and accordingly you will find, at page 300 of his Treatise on Inflammation, a chapter entitled 'Of Collections of Matter without Inflammation.'"

Professor Thomson doubts, however, "whether these collections of matter, said to be formed without inflammation, would not have been more properly denominated scrofulous abscesses or chronic suppurations. I am disposed to believe (says he), that in whatever texture or organ of the body scrofula manifests itself, there inflammation will be found to exist The phenomena, it is true, of inflammation, both local and constitutional, are modified by the existence of the scrofulous diathesis; but they are, I believe, always present in such a degree as to justify us in giving to them the name of inflammation, and in classing most, if not all local scrofulous affections, among inflammatory diseases. When the indolent swellings, of which Mr. Hunter speaks, occur near to the surface of the body, that part feels warmer than usual, as may be felt in white swellings of the joints. The swelling also is either preceded or accompanied with some degree of pain, though, when the affection is internal, the patient may not always be very accurate with regard to the precise state of this pain. When cut into, the parts also affected with scrofulous swellings are always found more vascular than usual; in short, all the symptoms occur by which the state of inflammation is characterized."—(*On Inflammation, p.* 313, 314.) In another place Dr. Thomson admits, that the matter which is formed in chronic suppurations does not always accurately resemble that which is formed in acute abscesses; yet he contends, that it is so analogous both in its physical and chemical characters, as well as in the circumstances in which it is produced, that he can see no reason why it should not be called pus or a puriform fluid.—(*P.* 315.) Sir A. Cooper also inculcates the common doctrine, that the formation of matter is preceded by inflammation, which, he says, in healthy persons is active, while in the debilitated and scrofulous, it is often very slight, and the pus produced generally less perfect.

Sometimes there is even such a change of action that the products entirely differ, being in scrofulous abscesses serous and curd like, or even chalky.—(*Lectures, &c. vol.* 1, *p.* 120.)

QUALITIES OF PUS.

True pus has certain properties, which, when taken singly, may belong to other secretions, but which, conjointly, form the peculiar character of this fluid, viz. globules swimming in a fluid which is coagulable by a solution of the muriate of ammonia, which no other animal secretion is, and, at the same time, a consequence of inflammation. This fluid, like serum, is coagulable by heat. "Pus also contains abundance of fibrin: if water be poured upon pus until the solid part, which remains at the bottom of the vessel, be entirely deprived of its serum and globules, numerous portions of fibrin are found remaining, and although not exactly of the same size, yet they have a great uniformity of appearance. Thus pus is composed of serum, fibrin, and globules; and (says Sir A. Cooper) if I were to hazard a theory upon this subject, I should say that pus was composed of the constituent parts of the blood, slightly changed in their character by inflammation."—(*Lectures, vol.* 1, *p.* 121.)

The colour and the consistence of pus are the two qualities which first attract the notice of every the most superficial observer. The colour arises from the largest portion of this fluid being composed of very

small round bodies, much resembling the globules of cream. The fluid in which the globules of pus swim, might at first be supposed to be the serum of the blood, for it coagulates with heat like the latter fluid. Pus is also probably mixed with a small quantity of coagulating lymph; as it partly coagulates after it is secreted. However, the fluid part of pus is found to have properties which serum has not. There being a similarity between pus and milk, experiments have been made to ascertain whether the fluid of pus could be coagulated with the gastric juice of animals: but no coagulation could be effected in this manner; a solution of muriate of ammonia made the fluid part of pus coagulate; but not any other secretion or natural fluid; and hence it was concluded, that whenever globules were found swimming in a fluid coagulable by muriate of ammonia, the matter was to be considered as pus.

The proportion which the white globules bear to the other parts of pus, depends on the health of the parts producing the discharge. When the globules are very abundant, the matter is thicker and whiter, and is called healthy pus; the meaning of which is, that the solids which produced it are in good health; for these appearances in the matter are no more than the result of certain salutary processes going on in the solids, the effect of which processes is to produce the disposition on which both suppuration and granulation depend.—(*Hunter.*)

Pus is specifically heavier than water, and is probably about as heavy as blood.

Besides the above properties, pus has a sweetish, mawkish taste, very different from that of most other secretions; and the same taste takes place, whether it is pus from a sore, or an irritated inflamed surface.

Pus has a smell in some degree peculiar to itself; but this differs in different cases. Some diseases, it is said, may be known by the smell, as, for instance, a gonorrhœa.

Pus sinks in water; mucus floats. Pus communicates to water a uniformly troubled white colour; mucus gives the appearance of stringy portions floating in it. Mucus is said to be more readily dissolved by sulphuric acid than pus is. It has also been asserted, that if water be added to such solutions, the pus is precipitated to the bottom of the vessel; while the mucus, instead of being completely precipitated, forms swimming flakes. A solution of caustic alkali dissolves both pus and mucus; but when water is added, pus is said to become separated, but not mucus.

Though solutions in chemical menstrua and precipitations have been thought a test of the distinction between these two fluids, yet the method has been thought absurd and unphilosophical. It has been conceived that all animal substances whatever, when in solution either in acids or alkalies, would be in the same state, and, therefore, that the precipitation would be the same in all. Calcareous earth, when dissolved in muriatic acid, is in that acid in the same state, whether it has been dissolved from chalk, limestone, marble, or calcareous spar; and precipitations from all are the same. Hence, the experiments were made on organic animal matter, such as muscle, tendon, cartilage, liver, and brain; and on inorganic, such as pus and the white of an egg. All these substances were dissolved in sulphuric acid, and precipitated with potassa. Each precipitation was examined with such magnifiers as plainly showed the forms of the precipitates, all which appeared to be flaky substances. The precipitate by ammonia had exactly the same appearance. The same appearances were seen, when the above kinds of animal matter were dissolved by caustic potassa, and precipitated with the muriatic acid. A flaky substance, void of any regular form, composed each precipitate.—(*Hunter.*) For additional observations on the tests of pus, and an account of those suggested by Dr. Young and Grasmeyer, see the *First Lines of the Practice of Surgery, last edition.*

Pus does not irritate the particular surface which secretes it, though it may be very irritating to any other. Hence, no suppurating surface of any specific kind can be kept up by its own matter: if this had not been the case, no sore of a specific quality, or producing matter of an irritating kind, could ever have been healed. This is similar to every other secretion of stimulating fluids, as the bile, tears, &c. which fluids do not stimulate their own glands or ducts, but are capable of stimulating any other part of the body.—(*Hunter.*)

Whenever a real disease attacks either the suppurating surface, or the constitution, the production of true pus ceases, and the fluid becomes changed in some measure, in proportion to these morbid alterations. In general, it becomes fetid, thinner, and more transparent, and partakes more of the nature of the blood, as is the case in most other secretions under similar circumstances. *Sanies* is the term usually applied by surgeons to pus in this degenerated state. This unhealthy sort of matter has more of the serum, and frequently more of the coagulating lymph in it, and less of the combination, which renders it coagulable by a solution of muriate of ammonia. It has also a greater proportion of the extraneous parts of the blood, which are soluble in water, such as salts; and it has a greater tendency than true pus to become putrid. Such unhealthy matter may even be irritating to the surface which produces it.

The secretion of matter is often suspended in fevers: while the constitution is thus disturbed, a sore will frequently appear almost dried up; but on the subsidence of the fever, its surface will again secrete pus in abundance. This is a fact which every young dresser must have noticed. A similar check to the secretion of pus is also produced when a sore, or the parts immediately around it, are attacked by fresh inflammation. The diminished quantity of pus is likewise changed in its qualities, as it becomes a thin ichor, or a red fluid, composed of serum and red particles.—(See *A. Cooper's Lectures, p.* 123, *vol.* 1.)

The discharge, when of an irritating sort, is more stimulating to the adjoining parts with which it comes in contact, than to its own secreting surface. In this manner it frequently produces excoriation of the skin and ulceration. Thus the tears excoriate the skin of the cheek, in consequence of the quantity of salts which they contain. From this effect, matter has been called corrosive, a quality which it has not; the only property which it possesses being that of irritating the parts which it touches so as to cause their absorption.—(*Hunter.*)

When the vessels thus lose the power of producing good pus, they also lose more or less the power of forming granulations. This may depend on some deviation from the due structure and action which such vessels should possess, in order to be qualified for the performance of these two operations.

Pus, from several circumstances, would appear in general to have a greater tendency to putrefaction than the natural juices have; but, perhaps, this is not the case with pure pus, which, when first discharged from an abscess, is commonly perfectly sweet. There are, however, some exceptions to this; but these depend on circumstances entirely foreign to the nature of pus itself. Thus, if the abscess has any communication with the air while the matter is confined in it; or if the collection has been so near the colon, or rectum, as to have been infected by the feces, then we cannot wonder that the matter should become putrid. When blood is blended with pus; when sloughs are mixed with it; when the parts forming the seat of the abscess are in a gangrenous state from an erysipelatous affection, the matter has a greater tendency to putrefy than the pure pus discharged from sound abscesses or healing sores. Pure matter, though easily rendered susceptible of change by extraneous additions, is in its own nature tolerably uniform and immutable. It appears so unchangeable, that we find it retained in an abscess for weeks, without having undergone any alteration. These qualities, however, only belong to perfect pus. If a healthy sore inflames, the matter now produced from it, though unmixed with extravasated blood, or dead solids, becomes much sooner putrid, and much more irritating than the discharge formed before this alteration of the ulcer.—(*Hunter.*)

In the preceding paragraph it is stated, that matter frequently remains unchanged in abscesses for weeks. This expression of Hunter's is not strictly correct; for it is well known, that the surfaces of the cavities of abscesses are always absorbing, as well as secreting ones; consequently, there must be a continual mutation going on in the contained matter.

When there are diseased bones, or other extraneous bodies, exciting irritation, sometimes even in so great a degree as to make the vessels bleed, and often wound

them, the matter is always found to be very offensive. This state of the discharge is one mark of a diseased bone.

The discharge of an unhealthy sore blackens silver probes and preparations of lead. This effect is imputed, by Dr. Crawford, to the sulphuretted hydrogen gas generated in the matter.—(*Phil. Trans. vol.* 80, *year* 1790, *p.* 385.) Farther interesting observations on the nature of pus may be found in an Essay on the Differences between Pus and Mucus, by Dr. Darwin, jun.; also in Dr. G. Pearson's Paper in Philos. Trans. 1811.

USE OF PUS.

By some it is supposed to carry off humours from the constitution. Suppuration is sometimes regarded as a constitutional disease changed into a local one, which constitutional malady is discharged, or thrown out of the body, either in the form of pus or together with this fluid. Critical abscesses have been thought to be cases of this sort. Suppuration has also been imagined to carry off local complaints from other parts of the body, on the old principle of derivation or revulsion. For this reason sores or issues are often made in sound parts before other sores are dried up. Suppuration is sometimes excited with a view of making parts, such as indurated swellings, dissolve into pus; but I have endeavoured to show that no dissolution of the solids is concerned in the production of pus.

A secretion of pus is looked upon as a general prevention of many or of all the causes of disease. Hence, issues are made to keep off universal as well as local diseases. However, the use of pus is perhaps unknown; for it is formed most perfectly from healthy sores, and in healthy constitutions; and large discharges from parts not very essential to life produce very little change in the constitution, and as little upon being healed up, whatever some may suppose to the contrary. —(*Hunter.*)

This is certainly the case with many old ulcers, the suppuration from which seems to have little or no effect in impairing the health. Nor is there any real reason to be afraid of healing such ulcers, when possible, lest a worse disease should follow from the stoppage of a discharge to which the system is supposed to be so habituated that the continuance of it must be essential to health.

Every one knows that when there is no interference of art, that is, when the surface of a sore is left uncovered, the thin part of the matter evaporates, and the thick part dries and forms a scab. Nature, therefore, seems to have designed, that one use of pus should be to make a cover, or protection for ulcerated surfaces. But I cannot agree with what has been asserted (*Hunter*), that the natural healing of a sore under a scab takes place more quickly than when surgical dressings are employed.

On ulcers, as would appear from modern microscopical observations, "the coagulated pus is rendered tubular by the extrication of its carbonic acid gas, and these tubes, or canals, are immediately filled with red blood, and thus connected with the circulation." If this point were established, Sir Everard Home conceives, that there would then be little difficulty in making out the succeeding changes, by means of which the coagulated pus afterward becomes organized.—(*On the Conversion of Pus into Granulations or new Flesh, in Phil. Trans. vol.* 109, *p.* 109, *Lond.* 1819.) These statements are curious, and ought to have been noticed in the article *Granulations*, to which they more immediately relate. I do not imagine, however, that nature will let us trace much farther the secrets here referred to.

Among the secondary uses of suppuration may be mentioned, opening a communication between a disease and the external surface of the body; forming a passage for the exit of extraneous bodies, &c.

TREATMENT WHEN SUPPURATION MUST TAKE PLACE.

In cases of inflammation, arising from accident, but so circumstanced that we know suppuration cannot be prevented, the indication is to moderate the inflammation, which, if the powers are great, and the injury done considerable, will probably be very violent. If the constitution should also be much affected, certain general means are proper, such as bleeding, purging, and nauseating medicines. While the constitution is severely disturbed, suppuration cannot take place in the most favourable manner. In these cases, also, such medicines as produce a gentle perspiration greatly relieve the patient: for instance, the pulv. ipecac. comp.; antimonials; liq. ammon. acet.; saline draughts, &c. Opiates may produce a temporary diminution of action; but they do not always have this desirable effect, and in some constitutions they increase the general irritability of the system, and seriously aggravate the inflammatory action.

The applications to inflammations which are to suppurate and form an abscess commonly used are, poultices and fomentations. These, however, appear to be applied without much critical exactness or discrimination; for they are applied before suppuration has taken place, and when this event is not desired; and they are also applied after suppuration has taken place. With respect to suppuration itself, abstracted from all other considerations, the indication cannot be the same in every state; but if poultices and fomentations are found to be of real service in the two stages of the disease, there must be something common to both for which they are of service, independently of simple suppuration. Poultices are useful when the inflammation attacks the skin, either in the first instance, or after an abscess has approached so near the skin that this becomes secondarily affected. This benefit appears to arise from the skin being kept soft and moist. Such is the use of a poultice in inflammation, either before or after suppuration, until the abscess is opened. But when poultices and fomentations are applied to inflamed parts, in which we wish to avoid suppuration, reason and principle will not justify the practice, though such applications may be proclaimed by experience to be very proper.—(*Hunter.*)

TREATMENT AFTER SUPPURATION HAS TAKEN PLACE.

When suppuration cannot be stopped or resolved, it is in general to be promoted.

How far suppuration can be usefully promoted by medicines or applications is questionable; but attempts are generally made, and for this purpose suppurating cataplasms and plasters, composed of the warm gums, seeds, &c. were formerly much recommended. Mr. Hunter doubted whether such applications had any considerable effect in the way intended; for if they were put on a sore, they would hardly increase the discharge from it, and perhaps even diminish it. However, in many cases in which the parts are indolent and hardly admit of true inflammation, in consequence of which a perfect suppuration cannot take place, stimulating the skin brings on a more salutary, and, of course, a quicker inflammation. Thus the antimonial ointment and blistering the skin over chronic swellings and abscesses, are sometimes indicated.

These applications have been found, however, to bring the matter more quickly to the skin, even in the most rapid suppurations. This effect has been mistaken for an increased formation of pus; but this consequence can only follow in cases in which the inner surface of the abscess is within the influence of the skin. The accelerated progress of the matter to the surface of the body arises from another cause, viz. the promotion of ulceration in the parts, between the collection of matter and the cuticle.

Emollient poultices are commonly applied to inflamed parts, when suppuration is known to have taken place. These can have no effect upon suppuration, except that of lessening the inflammation, or rather, making the skin more easy. The inflammation must have reached the skin before poultices can have much effect, for they can only affect that part. The ease of the patient, however, should be considered, and we find that fomentations and poultices are often beneficial in this way. By keeping the cuticle moist and warm, the sensitive operations of the nerves of the parts are soothed. On the contrary, if the inflamed skin is allowed to dry, the inflammation is increased; and as suppuration is probably not checked by the above treatment, it ought to be put in practice. As warmth excites action, the fomentation should be as warm as the patient can bear without inconvenience.—(*Hunter.*)

"The local treatment in phlegmonous abscesses (as Professor Thomson observes) is still more simple than that by which we endeavour to procure resolution. It

consists almost solely in the application of a moderate degree of warmth and moisture to the inflamed part, either by means of fomentations or poultices. The manner in which these means act in promoting suppuration is unknown. Independently of their temperature, it seems very doubtful whether fomentations and poultices have any power of promoting suppuration in the parts to which they are applied. They keep the cuticle moist and warm, they promote perspiration, they sooth and allay pain in many inflammations, and these are probably the only immediate effects which they produce. The rest is the work of nature. In suppurations attended by very severe pain, the use of warm fomentations is often found to afford singular relief; not only by their effect in easing pain, but also by their seeming to shorten the duration of the suppurative stage. In the cases of suppuration in which they give relief, they should be repeated every four or six hours. The most common way of employing them is by wringing linen or woollen cloths out of warm water, and applying these to the inflamed part, of as high a temperature as the feelings of the patient can bear. Decoctions of herbs were formerly much employed in the way of embrocation, and were then and are still, by many practitioners, supposed to possess peculiar virtues in promoting suppuration. Whether embrocations with the narcotic herbs might not in some cases be beneficial, by producing a sedative effect in allaying pain, I am unable to say, though I am inclined to believe that even they act chiefly by their warmth and moisture. In cases where you find it necessary to use an embrocation with herbs, the flowers of chamomile may in general be substituted in place of the leaves or flowers of almost every other plant. These flowers readily imbibe and retain moisture. They are, when moist, of a soft consistence, and can be easily moulded to the figure of the parts to which they are applied."—(*Thomson's Lectures, p.* 333.) Oatmeal, crum of bread, and especially linseed meal, are the ingredients mostly preferred in this country for emollient poultices. When bread is used, it is generally boiled in milk. The observations, however, which have been offered on poultices in another place, are here equally applicable.—(See *Inflammation.*)

OF THE TIME WHEN ABSCESSES SHOULD BE OPENED.

As abscesses, wherever formed, must increase that part of the cavity which is next to the skin more quickly than the bottom, they must become, in some degree, tapering towards the latter part, with their greatest breadth immediately under the skin. This shape of an abscess, when allowed to take place, is favourable to its healing, for it puts the bottom, which is the seat of the disease, more upon a footing with the mouth of the abscess than it otherwise could be. As the bottom or part where the abscess began is more or less in a diseased state, and as the parts between the seat of the abscess and the external surface are sound parts, having only allowed a passage for the pus, they of course have a stronger disposition to heal than the bottom has.

To keep the mouth of an abscess from healing before its bottom, the collection of matter should be allowed to break of itself; for, although abscesses in general only open by a small orifice, more especially when sound, yet in such cases the skin over the general cavity of the matter is so thinned, that it has very little tendency to heal, and often ulcerates and makes a free opening. If the latter event should not spontaneously occur, it may now be more easily obtained by the interference of the surgeon.

Abscesses which are the most disposed to heal favourably, are the quickest in their progress to the skin, and the matter comes to the surface almost at a point; the swelling is not so conical as in other cases; and when it bursts, the orifice is exceedingly small. On the other hand, when there is an indolence in the progress of the abscess, the collection spreads more, or distends the surrounding parts in a greater degree, in consequence of their not being so firmly united by inflammation in the one as they are in the other instance; nor will ulceration so readily take the lead, and the matter will come to the skin by a broad surface, so as to thin a large portion of the cutis.—(*Hunter.*)

It may be set down as a general axiom, that all phlegmonous abscesses should be allowed to break, and not be opened by the surgeon. When punctured unnecessarily or prematurely, they never heal so favourably as when left to themselves.

Particular cases, however, should be opened as soon as the existence of matter is ascertained. Abscesses should only be allowed to burst of themselves, when the confinement of the matter can do no mischief. Abscesses in the abdomen or thorax, under the cranium, near the eye, or in joints, should be mostly opened very soon. When suppuration takes place beneath ligamentous expansions or aponeuroses, which invariably retard the progress of the matter to the surface of the body, an early opening should be made. If this be not done, the matter spreads to a great extent, separating such ligamentous expansions from the muscles, and the muscles from each other, and as the pus cannot get to the surface of the body, the length of the disorder is of course increased. When matter is so situated as to be liable to insinuate itself into the chest or abdomen, or into the capsular ligaments of the joints, it is highly proper to prevent this extension of mischief, by making a timely opening into the abscess.

"Those abscesses ought to be opened early (says Professor Thomson) that are situated in parts through which the matter is liable to become widely diffused. This is particularly the case with abscesses that are situated on the fore part of the neck or in the cavity of the axilla, or by the side of the rectum. When matter is formed in the cavity of the axilla, if it does not speedily obtain an external outlet, it is very liable to pass up towards the clavicle in the course of the axillary plexus of nerves and vessels, or forwards under the pectoral muscle. I have repeatedly seen axillary abscess take both of these directions at the same time, forming one of the most painful and difficult cases to treat which occurs in the management of abscesses." Dr. Thomson also considers an early opening proper and necessary, when the matter is lodged, as in some cases of whitlow, in the sheaths of the tendons; when matter is formed under the periosteum; when it collects under fasciæ or in the vicinity of large arteries, joints, or the greater cavities of the body; and also when the abscess is deep-seated.—(See *Thomson's Lectures on Inflammation, p.* 336—338.)

With respect to making an early opening into abscesses situated near large arteries, I am not aware that any danger of the artery ulcerating in consequence of the nearness of the pus really exists. Therefore, some doubts may reasonably be entertained of the soundness of Professor Thomson's advice in this particular case, as the general rule of opening abscesses near large blood-vessels in an early stage of the disease, would be objectionable on the ground of the practice exposing the vessels themselves to injury. Indeed, this well-informed writer distinctly mentions, in considering the subject in question, that the arteries are not very susceptible of ulcerative absorption.—(*P.* 337.)

OF THE PLACE WHERE THE OPENING SHOULD BE MADE.

If a free opening is not required, or making one is not practicable, it is at least proper to make whatever opening can be made in a depending situation. By this means the matter will more readily escape, and all pressure arising from the confinement or lodgement of pus will be prevented. A very small degree of pressure on that side of the abscess which is next to the skin may produce ulceration there: and although such pressure might not, in many cases, be so great as to produce ulceration at the bottom of the abscess, yet it might be sufficiently great to prevent granulations from forming on that side, and thereby retard the cure, as no union could take place but by means of granulations. The pressure is always most, and retards the formation of granulations in the greatest degree, at the most depending part of the abscess. Hence, if no opening be made in this situation, the upper part of the abscess readily heals to a small point, which becomes a fistula.

When circumstances forbid making an opening at the most depending part of an abscess, perhaps nothing more can be done, than to evacuate the matter as often as necessary, and gently to compress the sides of the abscess together, if the situation of the case admit of the practice.

But abscesses are not always to be opened at the most depending part. The distance between the mat

ter and the skin at this part is the common reason against the method. If an abscess is rather deeply situated, and points in a place which is higher than where the collection lies, it is proper to make the opening where the conical eminence, or, as it is termed, the *pointing*, appears. Thus, if an abscess should form in the centre of the breast, and point at the uppermost part, which is often the case, it would be improper to cut through the lower half of the mamma, in order to make a passage for the matter in that direction. If an abscess should form on the upper part of the foot, it would be wrong to make an opening through the sole of the foot to get at the most depending part of the abscess; for besides cutting such a depth of sound parts, a great many useful ones would be destroyed.

When the abscess does not point in a depending situation, as in the instances just cited, since the place where the matter threatens to open a passage is likely to be the future opening, and this situation is disadvantageous to the healing of the deep part of the abscess, it is generally best to let the collection of matter first burst of itself, and then dilate the opening as freely as necessary. By allowing abscesses to burst spontaneously, the opening is not so apt to heal as if made by art, and, therefore, is better in such situations.—(*Hunter.*)

In most cases, it is more advantageous even to cut through a certain thickness of parts, for the sake of obtaining a depending opening, than to make an opening where the pointing appears, that is, where the parts are thinnest, and the matter nearest the surface. This remark is highly worthy of remembrance, when there is no doubt of the existence of matter at the depending place, and when the parts to be divided are not important ones. Collections of matter beneath the fasciæ of the forearm and thigh particularly demand attention to this direction, as they commonly point where those ligamentous expansions are thinnest, not where the matter can most readily escape.

Abscesses in the sheath of the rectus abdominis should also be opened in a low situation.

DIFFERENT METHODS OF OPENING ABSCESSES.

All abscesses will naturally burst of themselves, unless the matter be absorbed, and in general, they ought to be allowed to take this course. There are, however, as I have already explained, particular circumstances which require an early opening; but, when the skin over the abscess is very thin, it is not of so much consequence whether the case be permitted to burst of itself, or it be opened by the surgeon.

When abscesses are large, it is generally necessary to open them by art, whether they have burst of themselves or not, for the natural opening will seldom be sufficient for the completion of a cure; and although it may be sufficient for the free discharge of the matter, yet these abscesses will heal much more readily when a free opening is made; for the thin skin over the cavity granulates but indifferently, and therefore unites but slowly with the parts underneath.—(*Hunter.*)

Abscesses may be opened either by an incision, or by making an eschar with caustic. To the latter plan, however, many urge strong objections: the use of caustic is not usually attended with any advantage which may not be obtained by a simple incision; upon a tender inflamed part it gives much more pain; it is more slow in its effects; and the surgeon can never direct the operation of the caustic so accurately as to destroy exactly the parts which he wishes, and no more. If the eschar be not made deep enough, the lancet must, after all, be used. Caustic also leaves, after its application, a disagreeable scar, a consideration of some importance in opening abscesses about the female neck or face. To these numerous objections we have to add, that the eschar is very frequently ten or twelve tedious days in becoming detached.

When there is a redundance of skin, or when there is a good deal of it thinned, however, an opening made with caustic will answer, perhaps, as well as an incision. The application of caustic may also sometimes be advantageously resorted to when there is a good deal of indolent hardness around a small abscess.

The *calx cum potassa*, or the *potassa* alone, is the best caustic for opening abscesses. The part is first to be covered with a piece of adhesive plaster, which has a portion cut out exactly of the same figure and size as the opening intended to be made in the abscess. The best way of making the eschar is to dip the end of the caustic in water, and to rub it on the part till the skin becomes brown. The active substance is then to be immediately washed off with some wet tow, the plaster is to be removed, and an emollient poultice applied.

In almost all cases, it is better to use the lancet, or double-edged bistoury. Either of these instruments opens the abscess at once, and with less pain than results from the use of caustic; it occasions no loss of substance, consequently a smaller cicatrix; and by using it the opening may be made in the most advantageous direction, and of the exact size required.

DRESSINGS AFTER OPENING ABSCESSES.

When an abscess has burst of itself, and it is unnecessary to enlarge the opening, the only thing requisite is to keep the surrounding parts clean. The continuation of the same kind of poultice which was before used is, perhaps, as good a practice as any; and when the tenderness arising from the inflammation is over, lint and a pledget may be made use of, instead of the poultice.

But an abscess opened by a cutting instrument is both a wound and a sore, and partakes more of the nature of a fresh wound in proportion to the thickness of the parts cut. Hence, it is necessary that something should be put into the opening to keep it from healing by the first intention. If it is lint, it should be dipped in some salve, which will answer better than lint alone, as it will admit of being taken out sooner. This is advantageous, because such sores should be dressed the next day, or, at latest, on the second day, in order that the pus may be discharged again. When the cut edges of the opening have suppurated, which will be in a few days, the future dressings may be as simple as possible, for nature will in general complete the cure.

If the abscess has been opened with caustic, and the slough has either been cut out or separated of itself, the case is to be regarded altogether as a suppurating sore, and dressed accordingly.

Perhaps dry lint is as good a dressing as any, till the nature of the sore is known. If it should be of a good kind, the same dressing may be continued; but if not, then it must be dressed accordingly. Parts which at first appear to be sound, sometimes assume every species of disease, whether from indolence, from irritability, from scrofulous, and other dispositions. This tendency to disease arises in some cases from the nature of the parts affected, as, for instance, bone, ligament, &c.—(*Hunter.*)

[*Delpech, Chirurgie Clinique, t. 2, p. 353, et seq.* In the article *Suppuration*, I have explained that all abscesses are lined by a cyst, which is the organ by which the pus is secreted and absorbed, and also bounded. This is a subject, on which Professor Delpech has made some correct reflections. In all cases, he observes, wherever pus is formed and deposited, whether in what is improperly called a natural cavity; in what truly deserves this name; in some unusual space formed in the substance of parts; or on the surface of a wound; in every instance, a pseudo-membrane is found, and in none are the parenchyma of organs and the natural surfaces in contact with the purulent matter. Bichat had noticed the presence of the pseudo-membrane on the surface of a wound, forming the layers of common cellular substance, resisting the inflation of the part, and the injection of fluids into it; but, according to Delpech, he did not mark the constant connexion between this accidental organization and the formation of pus. In every example, the true organ by which pus is generated seems to Delpech to be the pseudo-membrane, which has a degree of organization imparted to it by the suppurative inflammation. He also explains, that it is not till ulcerated surfaces and the pleura are covered with an exudation of lymph, that pus is formed from them, and that when the matter is removed the pseudo-membrane is seen. Delpech declares, that no collection of matter is ever found on a serous membrane, without the latter being completely covered by a pseudo-membrane of more or less thickness; and that, if some points of it appear naked, or only coated with a very thin layer, as frequently happens, we always find flakes of pseudo membrane in the fluid, either entirely or partially detached. Another doctrine, much extended by Delpech beyond the limits usually given to it, is, that whenever the suppurative pseudo-mem

brane takes place, it is followed by a shrinking and contraction of the fibrous tissue, which it produces in the progress of the cure. To this principle he even refers the diminution and alteration in the shape of the chest after an empyema, that has been cured, and not to any positive changes, the result of the dwindled state of the lungs.—*Pref.*)

SURGERY, or CHIRURGERY, (from χειρ, the hand, and ἔργον, work), has been sometimes represented to be that branch of medicine, which principally effects the cure of diseases by the application of the hand alone, the employment of instruments, or the use of topical remedies.—(*Encyclopédia Méthodique, Partie Chir. t.* 1, *art. Chirurgie.*) Such definition, however, conveys but a very imperfect idea of the nature of this most useful profession, and, as applied to the present state of practice, cannot be said to be correct. It might indeed be applicable to that short unfavoured period of surgery, some centuries ago, when its practice was denounced by the Council of Tours, as unfit for the hands of priests and men of literature, and when the surgeon became little better than a sort of professional servant to the physician, the latter alone not only having the sole privilege of prescribing internal medicines, but even that of judging and directing when surgical operations should be performed. Then the subordinate surgeon was only called upon to execute with his knife, or his hand, duties which the more exalted physician did not choose to undertake; and, in fact, he visited the patient, did what was required to be done, and took his leave of the case, altogether under the orders of his master. In modern times, however, the good sense of mankind has discovered that surgery is deserving of an eminent rank among such arts as ought to be cultivated for the general benefit of society; that the man who is not himself accustomed to the performance of operations cannot be the best judge of their safety and necessity; and that, in every point of view, the surgical practitioner merits as much favour and independence in the exercise of his profession, as he whose avocation is confined to physic. Hence, the surgeon is now exclusively consulted about many of the most important diseases to which the human body is liable. Being no longer under the yoke of the physician, he follows the dictates of his own judgment and knowledge; he prescribes whatever medicines the case may demand, internal as well as external; and under the encouragement of an enlightened age, he sees his profession daily becoming more scientific, more respected, and more extensively useful.

Surgery, as Mr. Lawrence has stated, is a branch of that science and art which have diseases for their object. This science, considered generally, embraces the physical history of man. It investigates the construction of the human body, and its living actions; it inquires into the purposes executed by each part, and into the general results of their combined exertions; it observes the human organization under all the various modifications impressed on it by surrounding influences of all kinds; and it draws from these sources the rules for preserving health, and removing disease. The practical application of these rules constitutes the *art of healing*, or rather of *treating disease* (for, in many cases, we are unable to *heal*, and do not even attempt it); while the assemblage of facts and reasonings on which these practical proceedings are grounded make up the *science* of medicine.

By some writers, physic is said to have for its object the treatment of internal, surgery that of external, diseases. This definition, however good and plausible it may at first appear, can only be received with numerous exceptions in regard to modern practice: for instance, the psoas abscess; stone in the bladder; polypi and scirrhus of the uterus; stricture of the œsophagus; an extravasation of blood within the skull, in consequence of accidental violence; are universally allowed to be strictly surgical cases; yet no man in his senses would call these disorders external.

As Mr. Lawrence has pertinently observed, "Nature has connected the outside and inside so closely, that we can hardly say where one ends and the other begins. She has decreed that both shall obey the same pathological laws; and has subjected them to such powerful mutual influences, that we cannot stir a step in investigating the diseases of either, without reference to the other. How deep would the domain of surgery extend according to this view? Half an inch or an inch? The entrance of the various mucous membranes presents a series of puzzling cases; and the distribution of diseases in these situations, between the two branches of the profession, is quite capricious. How far is the surgeon to be trusted? He is allowed to take care of the mouth. Where is he to stop? At the entrance of the fauces—in the pharynx—or in the œsophagus? Inflammation and ulceration of the throat from syphilis belong to the surgeon; catarrhal affection of the same membrane to the physician. Polypus and ulceration of the nasal membrane are surgical; coryza is medical. The affections of the bones and joints have been given to the surgeon; yet they can hardly be called external parts. In hernia and aneurism, there is external tumour; but it is produced by displacement or disease of organs that are quite internal.

"When we look to the nature and causes of disease, the absurdity of the distinctions now under consideration is still more apparent, and the inseparable connexion between the interior and exterior of our frame more obvious. Internal causes produce external disease, as we see in erysipelas, carbuncle, nettle rash, gout, œdema; while external agencies affect inward parts, as in catarrhal rheumatic affections, in various inflammations of the chest and abdomen."

Others have defined surgery to be the mechanical part of physic, "*quod in therapeia mechanicum*;" but, although this has obtained the assent of so eminent a modern surgeon as Richerand of Paris (*Dict. des Sciences Médicales, t.* 5, *p.* 85), I believe few on this side of the water will be of his opinion. As Mr. J. Pearson has observed, "Many people have imagined, that when a man has learned the art of dressing sores, of applying bandages, and performing operations with a little dexterity, he must necessarily be an accomplished surgeon. If a conclusion so gross and fallacious had been confined to the vulgar and illiterate, the progress of scientific surgery would have suffered little interruption: but if young minds are directed to these objects, as the only important matters upon which their faculties are to be exercised; if the gross informations of sense constitute the sum of their knowledge; little

more can be expected from such a mode of study than servile imitation, or daring empiricism. Indeed, some people have affected to oppose surgery as an *art*, to medicine as a *science*; and if their pretensions were justly founded, the former would certainly be degraded to a mere mechanical occupation. But it is not very easy to comprehend the grounds of such a distinction. The internal and external parts of the body are governed by the same general laws during a state of health; and if an internal part be attacked with inflammation, the appearances and effects will bear a great similarity to the same disease situated externally; nor are the indications of cure, in general, materially different. If by science, therefore, be meant 'a knowledge of the laws of nature,' he who knows what is known of the order and method of nature, in the production, progress, and termination of surgical diseases, merits as justly the title of a scientifical practitioner as the well-educated physician. The practical parts of physic and surgery are very frequently disunited; but their theory and principles are indivisible, since they truly constitute one and the same science."—(*Principles of Surgery, Preface.*)

As a learned Professor notices, the limits between physic and surgery are not very precisely marked, and the respective functions of the physician and surgeon, long as those names have existed, are still but very inaccurately defined. "The most superficial acquaintance with the symptoms, progress, and termination of the various morbid affections to which the human body is liable, must be sufficient to convince every unprejudiced inquirer, that there is but a slight foundation, if indeed there be any, for this distinction in the nature of the diseases which these practitioners are required to treat, or in the modes of treatment by which the diseases themselves may be cured or relieved. Experience has long shown that the use of internal remedies is not only required in a large proportion of the diseases which are regarded as strictly chirurgical, but also, that there are few diseases which come under the care of the physician, in which morbid affections, requiring the manual aid or practical skill of the surgeon, do not frequently occur.

"The treatment of febrile and internal inflammatory diseases, it will be allowed, belongs exclusively to the province of the physician, wherever the distinction between physician and surgeon has been introduced, and is rigidly observed; yet, in some species of fevers, and in all internal inflammatory diseases, blood-letting is often the principal, if not the only remedy that is required. But this is an operation, however urgent the necessity for it be, which from engagement the physician cannot, and from the fear of degrading his province of the profession will not, perform. Retention of urine not unfrequently takes place in symptomatic febrile diseases, and this is an affection which does not always yield to the use of internal remedies; but it is an affection also, from the painful uneasiness which it immediately excites, as well as from the danger which it threatens, that will not admit of delay. When internal remedies, therefore, fail in relieving the patient, the urine must be speedily drawn off by means of a chirurgical operation; otherwise inflammation, mortification, and rupture of the bladder must necessarily ensue. Febrile and internal inflammatory affections terminate not unfrequently in the formation of fluids, which it is necessary to let out by a chirurgical operation; and abscesses, fistulous openings, and ulcers are formed, which require the aid of the surgeon. In patients, also, affected with severe febrile diseases, from being long fixed down to their beds in one position, some of the parts of the body, upon which they rest, occasionally acquire a disposition to mortify, larger or smaller portions of the skin and subjacent cellular membrane becoming dead, separate from the living parts, and sores are formed, which are but too often the subject of unavailing chirurgical practice. To employ, in the different stages of this species of mortification, from its first commencement to the complete separation of the dead parts, and the formation of a new skin, the appropriate external and internal remedies, requires a greater share of chirurgical skill than can reasonably be expected in those who make a profession solely of physic. Unhappy, therefore, must be the lot of that patient, who, in circumstances similar to those which I have described, has the misfortune to have for his sole medical attendant a physician ignorant of surgery.

"But (continues Professor Thomson) if a knowledge of surgery be necessary to the student who intends to practise physic, the knowledge of physic, on the other hand, is no less necessary to him who intends to devote his attention exclusively to the profession of surgery; for, indeed, there are few chirurgical diseases, which are not, in some period or another of their existence, accompanied by morbid affections of the same nature with those which fall properly, and most frequently, under the care of the physician. It will only be necessary to mention, as examples of these affections, the symptomatic fever which attends inflammation, whether this affection has been induced by external injury, or has occurred spontaneously in the body from internal disease; the hectic fever, supervening to long-continued processes of suppuration; the febrile state, and other morbid affections, which are sometimes brought on by the too sudden and injudicious use of mercury; bilious fevers, and the various derangements of the digestive organs, which are sometimes the cause, and at other times the consequence, of local diseases; the nervous affections, such as apoplexy, convulsions, paralysis, and mania, which arise not unfrequently from injuries of the head; and locked jaw, or tetanus, which, in warm climates particularly, is so very liable to be induced by punctured wounds. These are morbid affections, the proper study and treatment of which, when they occur without local injury, are supposed to belong to the physician, rather than the surgeon; but occurring very frequently, as they do in chirurgical diseases, and always modifying or aggravating the effects of these diseases, ignorance of their nature, relations, and modes of cure, is not only inexcusable, but highly criminal in the practitioner who ventures to undertake their treatment."—(*Thomson's Lectures on Inflammation, Introduction.* Also, *J. R. C. Boltman, Tentamen, ostendens Chirurgiam a Medicina haud impune separari*, 12*mo. Rintel.* 1803.)

From what has been stated, I think it very certain that there never can be a complete and scientific division of the healing art into physic and surgery; and that all attempts to distinguish the numerous diseases and injuries of the human body into medical and surgical cases must, in a great measure, be decided by custom and the mutual agreement of practitioners, rather than by any rules or principles which are at all consistent.

Mr. Lawrence joins all the most judicious practitioners in believing, that the line of demarcation between surgery and physic cannot be easily traced; and he considers the distinction between them to be a mere matter of arbitrary usage. He employs the word *surgery* in its common acceptation; understanding it to include, 1st, Injuries of all kinds; 2dly, The greater part of external and local complaints; 3dly, Such internal affections as produce changes recognisable externally; for example, alterations of figure, colour, or consistence; 4thly, All cases requiring external topical treatment, operations, or manual proceedings of any kind. This view coincides very much with the catalogue of diseases treated of in the present work; yet, such is the difficulty of separating surgery from physic by any general definitions, that every man of experience will immediately recollect various exceptions to some of the foregoing principles of classification. Thus ascites, or dropsy, which is an internal disease productive of change of figure, and often requiring an operation, is usually regarded as a medical case.

In the earliest periods, the same men cultivated the whole field of medicine. The writings of Hippocrates, Galen, Celsus, Paulus Ægineta, Albucasis, &c. prove that the Greeks, Romans, and Arabians never had an idea of the human body being susceptible of only two classes of diseases, one of which formed the province of physic, while the other constituted a separate and distinct science, called surgery. They had no conception of two systems of pathology; one applicable to the exterior, the other to the interior parts of the body. They knew, as well as the best-informed practitioners of the present day, that though each organ has its particular function to perform, its office is not independent of, but closely connected with the use and perfect state of other organs. Hence, as Mr. Lawrence has noticed, the expression of Hippocrates is perfectly correct: "*Labor unus; consentientia omnia.*"

The numerous individual organs which make up the human body although various in structure and

office, are all intimately connected and mutually dependent. They are merely subordinate parts of one great machine; and they all concur, each in its own way, in producing one general result,—the life of the individual. All the leading arrangements are calculated to give a character of unity to the organization and living actions of our frame. There is a common source of nutrition for the whole body; a single centre of circulation; a common place of union for all sensations and volitions, for nervous energy of whatever kind. The various organs are not only intimately connected by the share which they severally take in executing associated and mutually dependent functions, they act and re-act on each other, often very powerfully, by those mysterious, or at least hitherto unknown, influences which we call sympathies. As the animal machine, although complicated in structure, is single; and as its living motions, although numerous and intricate, form one indivisible series, so a similar connexion runs through those changes of structure and functions, which constitute disease. Hence, there is *one anatomy* and *physiology;* and there can be only *one pathology.*—(*Lawrence.*) All the above-mentioned ancient writers treat successively of fevers, fractures, wounds, and nervous diseases; and none of them appear to have supposed, that there could be any disorders which really deserved to be called *external*, and others *internal*. Nor was it until the middle of the twelfth century, when the clergy were restrained from undertaking any bloody operation, that surgery was rejected from the universities, under the empty pretext, "*Ecclesia abhorret a sanguine,*" often expressed in its decrees, as Professor Thomson well observes, but never acted upon, except in this instance, by the church of Rome. It is to this epoch that we must refer the artificial separation of physic from surgery; the latter being abandoned to the laity, who in those ages of barbarism were totally illiterate.

It is an observation made by the celebrated Bichat, that two things are essentially necessary to form a great surgeon; viz. genius and experience. One traces for him the way; the other rectifies it; both reciprocally assist in forming him. Without experience genius would be unprofitably fertile; without genius experience would only be a barren advantage to him.—(*Œuvres Chir. de Desault. par Bichat, t.* 1, *Discours Prélim.*) Out of the large number of hospital surgeons who are to be met with in every country of Europe, and who enjoy ample opportunities of profiting by the lessons of experience, how few distinguish themselves or ever contribute a mite to the improvement of their profession! Opportunity without talents and an aptness to take advantage of it, is not of more use than light to a blind man. On the other hand, splendid abilities without experience can never be enough to make a consummate surgeon, any more than a man with the greatest genius for painting can excel in his particular art, without having examined and studied the real objects which he wishes to delineate. In short, as a sensible writer has remarked, "*Les grands chirurgiens sont aussi rares, que le génie, le savoir, et les talens.*"—(*Mém. de l'Acad. de Chir. t.* 1, *Pref. p.* 41, *edit.* 12*mo.*)

The description of the qualities which a surgeon ought to possess, as given by Celsus, is excellent as far it goes. A surgeon, says he, should be young, or at any rate not very old; his hand should be firm and steady, and never shake; he should be able to use his left hand with as much dexterity as his right; his sight should be acute and clear; his mind intrepid and pitiless, so that when he is engaged in doing any thing to a patient he may not hurry, nor cut less than he ought, but finish the operation just as if the cries of the patient made no impression upon him.—(*A. C. Celsi Med. Præf. ad lib.* 7.)

[The following judicious discrimination is from the pen of the late Professor Godman, and does honour to his head and heart.

"The difference between a surgeon and a mere operator may be estimated by contrasting them. The *surgeon* inquires into the causes and removes the consequences of constitutional or local disease; the *operator* inquires into the willingness of his patient to submit, and resorts to the knife. The *surgeon* relies on the restoration of the healthy actions by regimen and medicine; the *operator* relies on himself, and cuts off the diseased part. The *surgeon*, reflecting on the comfort and feelings of his patient, uniformly endeavours to save him from pain and deformity; the *operator* considers his own immediate advantage and the notoriety he may acquire, regardless of other considerations. The *surgeon* reluctantly decides on the employment of instruments; the *operator* delays no longer than to give his knife a keen edge. The *surgeon* is governed by the principles of the science; the *operator* most generally by the principle of interest; one is distinguished by the numbers he has saved from mutilation and restored to usefulness; the other by the number of cripples he has successfully made. The *surgeon* is an honour to his profession and a benefactor of mankind; the *mere operator* renders the profession odious, and is one of the greatest curses to which mankind, among their manifold miseries, are exposed."—*Reese.*]

By the word "*immisericors,*" as Richerand has observed (*Nosogr. Chir. tom.* 1, *p.* 42, *Edit.* 2), Celsus did not mean that a surgeon ought to be quite insensible to pity; but that during the performance of an operation this passion should not influence him, as all emotion would then be mere weakness. This undisturbed coolness, which is still more rare than skill, is the most valuable quality in the practice of surgery. Dexterity may be acquired by exercise; but firmness of mind is a gift of nature. Haller, to whom nature was so bountiful in other respects, was denied this quality, as he candidly confesses. "Although (says he) I have taught surgery seventeen years, and exhibited the most difficult operations upon the dead body, I have never ventured to apply a cutting instrument to a living subject, through a fear of giving too much pain."—(*Bibl Chir.* 1775, *vol.* 2.)

Surgery may boast of having had an origin that well deserves to be called noble; for the earliest practice of it arose from the most generous sentiment which nature has implanted in the heart of man, viz. from that sympathetic benevolence which leads us to pity the misfortunes and sufferings of others, and inspires us with an anxious desire to alleviate them. He who first saw his fellow-creatures suffer, could not fail to participate in the pain, and endeavour to find out the means of affording relief. Opportunities of exercising this useful inclination were never wanting. In the first ages of the world, man in his destitute state was under the necessity of earning, by force or stratagem, a subsistence which was always uncertain; and in the combats, into which this sort of life drew him, he frequently met with wounds and other injuries. Wherever the chase was in vogue as a means of livelihood or amusement; wherever broils and contests occasionally arose; and man was the same animal he now is, liable to various diseases and accidental hurts; there must have existed a necessity for surgery: nor can there be a doubt that the origin of this valuable practice is as ancient as the exposure of mankind to several of the same kinds of injuries as befall the human race at the present day. At length, wars became more frequent and extensive: wounds were consequently multiplied; and the necessity for surgical assistance was increased, and its value enhanced.

Among the ancients, the profession of medicine and surgery constituted a sacred kind of occupation, and the practice of it belonged only to privileged persons. Æsculapius was the son of Apollo. In the armies, the highest princes gloried in dressing the wounds of those who had fought the battles of their country. Among the Grecians, Podalirius, Chiron, and Machaon were not only distinguished for their valour, but also for their skill in surgery, as we learn from the poem of the immortal Homer. The value which was placed upon the services of Machaon by the Grecian army, may well be conceived from the anxiety which it evinced to have him properly taken care of when he was wounded in the shoulder with a dart. "O Nestor, pride of Greece (cries Idomeneus), mount, mount upon thy chariot! and let Machaon mount with thee! Hasten with him to our ships: for a warrior who knows, as he does, how to relieve pain and cure wounds, is himself worth a thousand other heroes."—(See *Iliad, lib.* xi.) Hippocrates was one of the first citizens of Greece: he nobly refused all the rich offers of several kings, enemies of his country, to entice him into their service; and, in particular, he disdained to accept those of Xerxes, whom he regarded as a barbarian.

It is in the immortal poems of the Iliad and Odyssey, that we find the only certain traditions respecting

the state of the art before the establishment of the republics of Greece, and even until the time of the Peloponnesian war. There it appears, that surgery was almost entirely confined to the treatment of wounds, and that the imaginary power of enchantment was joined with the use of topical applications.

In the cures recorded in the sacred writings of the Christian religion, the intervention of a supernatural power is always combined with what is within the scope of human possibility. The same character evinces itself in the infancy of the art in every nation. The priests of India, the physicians of China and Japan, and the jugglers of the savage or half-civilized tribes of the old and new continents, constantly associate with drugs and manual operations certain mysterious practices, upon which they especially rely for the cure of their patients. Such was also, no doubt, the character of the medicine of the Egyptians in the remote times, previous to the invention of the alphabet, and upon which so very little light is now thrown.

It is curious, however, to find, from some late observations made by the men of science who accompanied the French expedition to Egypt in 1798, that among the ruins of ancient Thebes there are documents which fully prove that surgery, in the early times of the Egyptians, had made a degree of progress, of which few of the moderns have any conception. It is noticed by Larrey, that when the celebrated French General Dessaix had driven the Mamelukes beyond the Cataracts of the Nile, the Commission of Arts had an opportunity of visiting the monuments of the famous Thebes, and the renowned temples of Tentyra, Karnack, Medynet Abou, and Luxor, the remains of which still display their ancient magnificence. It is upon the ceilings and walls of these temples that basso-relievos are seen, representing limbs that had been cut off with instruments very analogous to those which are employed at the present day for amputations. The same instruments are again observed in the hieroglyphics, and vestiges of other surgical operations may be traced, proving that, in these remote periods, surgery had made some considerable progress.—(*Larrey, Mémoires de Chir. Militaire*, *t.* 1, *p.* 233; *t.* 2, *p.* 223.)

We next come to the epoch when, by the union and arrangement of scattered facts, the science truly arose. Hippocrates, born in the island of Cos, four hundred and sixty years before the common era, collected the observations of his predecessors, added the results of his own experience, and composed his first treatises. In the hands of this great genius, medicine and surgery did not make equal progress. The former reached a high degree of glory. Hippocrates drew up the history of acute diseases in so masterly a style, that twenty past centuries have hardly found occasion to add any thing to the performance. But surgery was far from attaining the same degree of perfection. The religious veneration for the asylums of the dead, and the impossibility of dissecting the human body, formed an insurmountable obstacle to the study of anatomy. An imperfect acquaintance with the structure of animals, reputed to bear the greatest resemblance to man, could only furnish venturesome conjectures or false inferences. These circumscribed notions sufficed for the study of acute diseases. In these cases, the attentive observation of strongly marked symptoms, and the idea of the operation of a salutary principle, derived from remarking the regular succession of such symptoms, and their frequently beneficial termination, enlightened the physician in the employment of curative means; while surgery, deprived of the assistance of anatomy, was too long kept back in an infant state. Whatever praises may have been bestowed on those parts of the works of Hippocrates particularly relating to surgery, and which amount to six in number (*de officina medici; de fracturis; de capitis vulneribus; de articulis vel luxatis; de ulceribus; de fistulis*), when compared with his other acknowledged legitimate writings, they appear only as the rough sketches of a picture by a great master.

Excepting the fragments collected or cited by Galen, we possess no work written by any of the successors of Hippocrates until the period of Celsus; which leaves a barren interval of almost four centuries. In this space lived Erasistratus, as well as Herophilus, celebrated for the sects which they established, and particularly for having been the first who studied anatomy upon the human body.

Celsus lived at Rome in the reigns of Augustus, Tiberius, and Caligula. He appears never to have practised the healing art, on which, however, he has written with much precision, elegance, and perspicuity. His work is the more precious, inasmuch as it is the only one which gives us information with regard to the progress of surgery in the long interval between Hippocrates and himself. The last four books, and especially the seventh and eighth, are exclusively allotted to surgical matter. The style of Celsus is so elegant, that he has generally been regarded quite as the Cicero of medical writers, and long enjoyed high reputation in the schools. His surgery was entirely that of the Greeks, notwithstanding he wrote at Rome: for, in that capital of the world, physic was then professed only by persons who had either come from Greece, or had received instruction in the celebrated schools of this native soil of all the arts and sciences.

Let us pass over the interval which separates Celsus and Galen. This latter was born at Pergamus in Asia Minor, and came to Rome in the reign of the Emperor Marcus Aurelius, where he practised surgery and physic about the year 165 of the Christian era.—(*Galeni Opera Omnia*, 1521, *edit. Aldi*, 5 *vols. in fol.*) These two sciences were at that time still united, or rather the possibility of completely dividing them had never been conceived; and though some writers of much earlier date speak of the division of physic into dietetical, chirurgical, and pharmaceutical, no such distinction was followed in practice. As Galen had been a surgeon, or more probably a general practitioner, at Pergamus, he continued the same profession at Rome; but, being soon attracted by the predominating taste of the age in which he lived to studies which more easily accommodate themselves to the systems and dazzling speculations of philosophical sects, he afterward neglected surgery, which strictly rejects them. His writings prove, however, that he did not abandon it entirely. His commentaries on the treatise of Hippocrates, *De Officina Medici*, and his essay on bandages, and the manner of applying them, show that he was well versed even in the minor details of the art. Besides, it is known, that he paid great attention to pharmacy; and in his work upon antidotes, chap. 13, he tells us himself, that he had a drug shop in the Via Sacra, which fell a sacrifice to the flames that destroyed the Temple of Peace and several other edifices in the reign of Commodus.

To Galen succeeded the compiler Oribasius, Œtius of Amida, a physician who lived towards the close of the fifth century, Alexander of Tralles, and Paulus Ægineta, so called from the place of his birth, though he practised at Rome and Alexandria. Paulus collected into one work, still justly esteemed, all the improvements which had been made in surgery down to his own time. He concludes the series of Greek and Roman physicians, and may be looked upon as the last of the ancients, unless it be wished to let the Arabians have a share in the honours of antiquity. "He appears," says Portal, "to be one of those unfortunate writers to whom posterity has not done justice. It seems as if he had been decried without having been read; for if pains had been taken to examine his works, he would neither have been regarded as a mere copyist, nor been called the 'ape of Galen,' with whom he does not always coincide. Nay, in some places, he ventures to oppose the doctrines of Hippocrates. He was perfectly acquainted with the practice of the ancients; and when he agrees with or differs from them, it is not from a spirit of contradiction, but because the reasons which led him to take one side or the other appeared to him well founded."—(*Portal, Hist. de l'Anat. &c. t.* 1, *p.* 123.) All now agree, that surgery is much indebted to him.—(See *R. A. Vogel, De Pauli Æginetæ Meritis in Medicinam imprimisque Chirurgiam*, 4*to. Gött.* 1768.) Afterward, the downfall of surgery followed that of all the other sciences, and from the capture of Alexandria by the Saracens under Amrou, Viceroy of Egypt, in 641, until the end of the tenth century, nothing prevailed but the dark clouds of ignorance and barbarism. The Arabians, who became masters of a great part of the Roman empire, dug up the Greek manuscripts which lay buried under the ruins of the libraries; translated them; appropriated to themselves the doctrines which they contained; impoverished them by additions; and transmitted to posterity only enormous compilations. In a word,

such are the treatises of Rhazes, Hali-Abbas, Avicenna, Averrhoes, and Albucasis, the most celebrated of the Arabian authors. Inventors of a prodigious number of instruments and machines, they appear to have calculated the efficacy of surgery by the richness of its arsenals, and to have been more anxious to inspire terror than confidence. As an instance of the cruelty of their methods, I shall merely notice, that in order to stop the bleeding after amputation, they plunged the stump in boiling pitch.

The fate of medicine was not more fortunate. In vain the school of Salernum, founded about the middle of the seventh century, made some attempts to revive its splendour. As a modern writer observes, medical science, seated on the same benches where the doctrine of Aristotle accommodated to religious opinions, was the subject of endless controversies, imbibed, as it were, by contagion, the argumentative and sophistical mania, and became enveloped in the dark hypotheses of scholastic absurdity.—(*Richerand, Nosogr. Chir. t.* 1, *ed.* 2.)

The universal ignorance (continues this author), the pretended horror of blood, the dogma of a religion which shed it in torrents for useless quarrels, an exclusive relish for the subtleties of the schools and speculative theories, are circumstances farther explaining the profound darkness which followed these empty labours. About the middle of the twelfth century (1163), the Council of Tours prohibited the clergy, who then shared with the Jews the practice of medicine and surgery in Christian Europe, from undertaking any bloody operation. It is to this epoch that the true separation of medicine from surgery must be referred. The latter was abandoned to the laity, the generality of whom, in those ages of barbarism, were entirely destitute of education. The priests, however, still retained that portion of the art which abstained from the effusion of blood. Roger Rolandus, Bruno, Gulielmus de Salicetus, Lanfranc, Gordon, and Guy de Chauliac confined themselves to commentaries on the Arabians; and, if the latter author be excepted, they all disgraced surgery by reducing it nearly to the mere business of applying ointments and plasters. Guy de Chauliac, however, the last of the Arabians, is to be honourably excluded from such animadversion. His work written at Avignon, in 1363, in the pontificate of Urban the Fifth, to whom he was physician, continued to be, for a long while, the only classical book in the schools. It may be observed, that as he imitated in every respect the other Arabian physicians, and like them thought that it did not become a priest to deviate from the austerity of his profession, he has passed over in silence the diseases of women.

At length, Antonio Beneveni, a physician of Florence, began to insist upon a truth of the highest importance to the extension of surgical knowledge, viz. that the compilations of the ancients and Arabians ought to be relinquished for the observation of nature. —(*De abditis Rerum Causis, Florent.* 1507, 4*to.*) A new era now began. The moderns were convinced, that by treading servilely in the footsteps of their predecessors, they should never even equal, much less surpass them. The labours of Vesalius also gave birth to anatomy, illuminated by which science surgery put on quite a different appearance in the hands of Ambroise Paré, the first and most eminent of the ancient French surgeons. For the credit of Italy, however, it should be recorded, that the sensible writings published in that country prior to the time of Paré had the greatest influence in creating a due sense of the value and importance of surgery, and in disposing men of talents and education to cultivate it as a liberal profession.

Obeying the dictates of his genius, Paré either compelled authority to yield to observation, or endeavoured to reconcile them. However, his superior merit soon excited the ignorant, the jealous, and the malignant against him; he became the object of a bitter persecution; and his discoveries were represented as a crime. Although he was the restorer, if not the inventor, of the art of tying the blood-vessels, the power of his persecutors compelled him to make imperfect extracts from Galen, and alter his text, in order to rob himself, in favour of the ancients, of the glory which this distinguished improvement deserved.

Surgeon of King Henry the Second, Francis the Second, Charles the Ninth, and Henry the Third of France, Paré practised his profession in various places, followed the French armies into Italy, and acquired such esteem, that his mere presence in a besieged town was enough to reanimate the troops employed for its defence. In the execrable night of St. Bartholomew, his reputation saved his life. As he was of the reformed religion, he would not have escaped the massacre, had not Charles the Ninth himself undertaken to protect him. The historians of those days (*Mém. de Sully*) have preserved the remembrance of this exception, so honourable to him who was the object of it; but which should not diminish the just horror which the memory of the most weak and cruel tyrant must ever inspire. "Il n'en voulut jamais sauver aucun (says Brantome) sinon maistre Ambroise Paré, son premier chirurgien, et le premier de la Chrétienneté; et l'envoya querir et venir le soir dans sa chambre et garderobe, lui commandant de n'en bouger; et disait qu'il n'était raisonnable qu'un qui pouvait servir a tout un petit monde, fût ainsi massacré."

Ambroise Paré was not content, like his predecessors, with exercising his art with reputation; he did not follow the example of the Quatre-Maîtres of Pitard, so justly celebrated for having composed the first statutes of the College of Surgeons at Paris, in the reign of St. Lewis, whom he had attended in his excursions to the Holy Land; and of several other surgeons, the fruits of whose experience were lost to their successors: he transmitted the result of his own experience in a work that is immortal.—(See *Œuvres d'Ambroise Paré, Conseiller et premier Chirurgien du Roi, divisées en* 28 *livres, in folio, edit.* 4*to. Paris,* 1535.)

His writings, so remarkable for the variety and number of facts in them, are eminently distinguished from all those of his time, inasmuch as the ancients are not looked up to in them with superstitious blindness. Freed from the yoke of authority, he submitted every thing to the test of observation, and acknowledged experience alone as his guide. The French writers are with reason proud of their countryman Paré to this day: they allege, that he must ever hold among surgeons the same place that Hippocrates occupies among physicians. Nay, they add, that perhaps none of the ancients or moderns are worthy of being compared with him.—(*Richerand, Nosogr. Chirurg. t.* 1.)

After the death of this great man, surgery, which owed its advancement to him, continued stationary, and even took a retrograde course. This circumstance is altogether ascribable to the contemptible state into which those who professed the art fell, after being united to the barbers by the most disgraceful association.

Pigrai, the successor of Ambroise Paré, was far from being an adequate substitute for him. A spiritless copier of his master, he abridged his surgery in a Latin work, where the unaffected graces of the original, the sincerity, and the ineffable charm, inseparable from all productions of genius, entirely disappeared. He received, however, equal praise from his contemporaries; doubtless, because he filled a high situation: but, as Richerand remarks, his name, which is to day almost forgotten, proves sufficiently that dignities do not constitute glory.

Rousset and Guillemeau distinguished themselves, however, in the art of midwifery; while Covillard, Cabrol, and Habicot enriched surgery with a great number of curious observations.—(See *Obs. Chir. pleines de Remarques curieuses, Lyon,* 1639, *in* 8*vo. Alphabet Anatomique, Genève,* 1602, *in* 4*to. Semains Anatomique; Question Chir. sur la Bronchotomie, Paris,* 1620, *in* 8*vo.*)

In the next or seventeenth century, a fresh impulse produced additional improvements. Then appeared in Italy Cæsar Magatus, who simplified the treatment of wounds (*De Rarâ Vulnerum Medicatione, libri* 2, *Venet.* 1616, *in folio*); Fabricius ab Aquapendente, even less praiseworthy as a surgeon than as a physiologist (*Opera Chir. Paris,* 1613, *in fol.*); and Marcus Aurelius Severinus, that restorer of active surgery.—(*De Efficaci Medicina, libri* 3, *Francofurt.* 1613, *in folio. De recondita Abscessuum Natura, libri* 7. *Neapoli,* 1632, *in* 4*to, and Trinembris Chirurgia, &c. Francofurt.* 1653, *in* 4*to.*) Among the English surgeons flourished Wiseman, who was the Paré of England (see *Several Chirurgical Treatises, Lond.* 1676, *in fol.*); and William Harvey, whose discovery of the

circulation of the blood had such an influence over the advancement of medical science in general, and that of surgery in particular, that he must be classed among the principal improvers of the latter profession.—(See *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus. Francofurti*, 1653, *in* 4*to.*) In Germany, Fabricius Hildanus (*Obs. et Curationum, Centuriæ* 6, 2 *vol. in* 4*to.* 1641), who was far superior, as a surgeon, to the Italian Fabricius. Scultetus, so well known for his work entitled *Armamentarium Chirurgicum, Ulmæ*, 1653, *in folio;* Purmann and Solingen, who had the fault of being too partial to the use of numerous complicated instruments.—(See *Cursæ Obs. Chir. Lipsiæ*, 1710, *in* 4*to. Manuale Obs. der Chirurgiæ, Amsterdam*, 1684, *in* 4*to.*)

Holland, restored to liberty by the generous exertions of its inhabitants, did not long remain a stranger to the improvement of surgery. This nation, so singular in many respects, presents us with one particularity which claims the notice of a medical historian. Ruysch, who was an eminent anatomist, and merits equal celebrity for his *Obs. Anatomico-Chirurgicarum Centuriæ, Amstelodam.* 1691, *in* 4*to.* carried with him to the grave the secret of his admirable injections.—(See also his *Thesaur. Anat. x.*, *in* 4*to. Adversariorum anatomicorum médico-chirurgicorum, Decad.* 3, *in* 4*to. Amstelodam.*) Roonhuysen also made a secret of his lever, which, before the invention of the forceps, was the only resource in difficult labours. Raw, who successfully cut fifteen hundred patients for the stone, took such pains to conceal his manner of operating, that Heister and Albinus, his two most distinguished pupils, have each given a different explanation of it. Such a disposition, which is extremely hurtful to the advancement of medical and surgical knowledge, would materially have retarded the progress of surgery in Holland, had not Camper, in the following century, effaced the imputation by the great number of his discoveries, and his zealous desire to render them public.

While great improvements were going on in Italy, England, and Holland, surgery languished in a humiliated state in France. The accoucheur Mauriceau (*Traité des Maladies des Femmes grosses, Paris*, 1668, *in* 4*to.*), Dionis (*Cours d' Opérations de Chirurgie, Paris*, 1707, 8*vo.*), Saviard (*Nouveau Recueil d' Obs. Chir. Paris*, 1702, *in* 12*mo.*), and Belloste (*Chirurgien d' Hôpital, Paris*, 1696, *in* 8*vo.*) were the only French surgeons of note, who could be contrasted with so many distinguished men of other nations. Richerand observes, that the splendid days of Louis the Fourteenth were in an iron age for discouraged surgery. And yet this monarch seems to have been personally interested in the melioration of this important art; for he was very nearly falling a victim to a surgical disease, a fistula in ano, and was not cured till after a great number of blundering operations and useless experiments.

Chronology teaches simply the history of dates. In the study of the sciences, the only method of impressing the memory with facts consists in connecting the epoch of them with the learned men by whom they have been illustrated. But the greatest surgeons of the eighteenth century have not altered the face of their profession, although they have powerfully contributed to its advancement. In surgery, as an author has remarked, some feeble rays always precede brilliant lights, and it approaches perfection in a very gradual way. In the last century, however, among the distinguished surgeons of France, there are two of extraordinary genius, round whom, as it were, all the others might be grouped and arranged, and whose names deserve to be affixed to the two most brilliant epochs of French surgery. These are, first, J. L. Petit, whose glory was shared by the Academy of Surgery; and, secondly, the celebrated Desault.

It is not with surgery as with physic, strictly so called: the epochs of the latter are distinguished by hypotheses: while those of surgery are marked by discoveries. The eminent men in this last branch of the profession have not, like the most renowned physicians, created sects, built systems, destroyed those of their predecessors, and constructed a new edifice, which in its turn has been demolished by other hands. All of them have been satisfied with combating ancient errors, discovering new facts, and continuing their art, the sphere of which they have enlarged by their discoveries, without making it bend under the yoke of systems which it would have ill supported.

The eulogy on J. L. Petit, delivered in the midst of the Royal Academy of Surgery, of which he was one of the first and most distinguished members, represents him as blending the study of anatomy with his amusements when a boy; and ardently seeking every opportunity to increase his knowledge by observation. He had had experience enough to publish at an early period of his life his *Traité sur les Maladies des Os, Paris*, 1705, *in* 12*mo.;* a work which for a century was esteemed the best upon the subject. His success was most virulently opposed by envious critics; and it was not till after more than thirty years of academical labours and extensive practice that he was unanimously chosen the head of his associates. This acknowledged superiority, however, was the more flattering, as the honour was obtained at a period when surgery was in a flourishing state in France, and when Petit held no office from which he could derive any influence unconnected with his personal merit. While Mareschal, La Peyronie, and La Martinière assured him of the royal favour, Quesnay, Morand, and Louis, who corrected his writings, made him speak a language which does honour to that famous collection to which he contributed his observations (see *Mémoires et Prix de l' Academie Royale de Chirurgie*, 10 *vols. in* 4*to.*), and in which, if some theoretical explanations be put out of consideration, nothing has lost its value by age. J. L. Petit was also the author of a "*Traité des Maladies Chirurgicales, et des Opérations qui leur conviennent. Ouvrage Posthume;*" a production that will always stand high in the estimation of the judicious surgeon.

The history of this epoch, so glorious for the profession of surgery, is completely detailed in the Memoirs and Prizes of the Royal Academy of Surgery; a work which is absolutely indispensable, and the various parts of which cannot be too often considered. In it are preserved the labours of Mareschal, Quesnay, La Peyronie, Morand, Petit, De la Martinière, Le Dran, Garengeot, De la Faye, Louis, Verdier, Foubert, Hevin, Pibrac, Fabre, Le Cat, Bordenave, Sabatier, Puzos, Levret, and several other practitioners, who, though less famous, contributed by their exertions and knowledge to form this useful body of surgical facts. Many of the preceding surgeons also distinguished themselves by other productions, which, however, I shall not here enumerate, as they are quoted in many other parts of this work.

To the foregoing list of eminent French surgeons must be added the names of La Motte, Ma tre-Jean, Goulard, Daviel, Ravaton, Mejean, Pouteau, David, and Frère Cosme.

While surgery was thus advancing in France, other nations were not neglectful of it. At this period flourished, in Great Britain, White, Cheselden, Douglas, the two Monros, Sharp, Cowper, Warner, Alanson, Bromfield, Pott, Kirkland, Hawkins, Smellie, and the two Hunters.

White's *Cases in Surgery*, 1770; Cheselden's *Treatise on the High Operation for the Stone, London*, 1723, *in* 8*vo.*, and his *Treatise on the Anatomy of the Human Body;* Douglas's Tract, entitled "*Lithotomia Douglassiana;*" Sharp's *Treatise of the Operations*, and his "*Critical Inquiry into the Present State of Surgery;*" *Monro's Works by his son; Warner's Cases in Surgery*, 1754, and his *Description of the Eye and its Diseases*, 1775; *Alanson's Treatise on Amputation; Pott's Chirurgical Works; Kirkland's Obs. on Fractures*, 1770; his *Thoughts on Amputation*, 1780; and his *Medical Surgery*, 1783; *Smellie's Midwifery;* and *John Hunter on the Blood, Inflammation, &c.;* his *Treatises on the Venereal Disease, Animal Economy, the Teeth*, and all the papers written by himself and his brother, in the *Phil. Trans. Med. Obs. and Inquiries*, and *Trans. of a Society for the Improvement of Med. and Chir. Knowledge;* are productions which reflect the highest credit on the state of surgery in England.

But of all these eminent men, none contributed more powerfully than Mr. Percival Pott to the improvement of the practice of surgery in England. His life, indeed, forms a sort of epoch in the history of the profession. Before his inculcations and example had produced a desirable change, the maxim of "*dolor medicina doloris*," as we learn from Sir James Earle, remained unrefuted. The severe treatment of the old school, in the operative part and in the applications

continued in force. The first principles of surgery, the natural process and powers of healing, were either not understood or not attended to; painful and escharotic dressings were continually employed; and the actual cautery was in such frequent use, that at the times when the surgeons visited the hospitals, it was regularly heated and prepared as a part of the necessary apparatus. Where shall we find more sensible or more truly practicable observations on the treatment of abscesses, than in Pott's excellent treatise on the fistula in ano? Where shall we meet with better remarks on the local treatment of gangrenous parts, than in his valuable tract on the mortification of the toes and feet? What author abounds with so many just observations on the injuries of the head, blended, it is true, with rather too great a partiality to the trepan, the so frequent necessity for which is now less generally acknowledged? His description of the inflammation and suppuration of the dura mater and of the treatment is matchless. The account which he has left us of the disease of the vertebræ, attended with paralysis of the limbs, is perhaps his most original production. His celebrated essay on fractures was also very original, and has had in this country considerable influence over the treatment of these injuries; but there can now be no doubt that the effects of position were exaggerated in this part of his writings, and that surgeons ought still to make every possible exertion to render their apparatus for broken bones more effectual.—(See *Fractures.*) A more really valuable production of this eminent surgeon is his remarks on amputation. The necessity for that operation in certain cases is there convincingly detailed; and the most advantageous period for its performance clearly indicated. The urgency for its prompt execution after particular injuries he has indeed so perfectly explained, that the late inculcations on the subject by Larrey and several other modern surgeons appear to be in a great measure anticipated; the only difference being, that Pott's remarks applied principally to compound fractures, while Larrey's refer to gun-shot wounds. All these, however, are cases of accidental violence, and, of course, should be treated upon the same general principles.

A longer comment on the writings and improvements of Percival Pott would here be requisite to do him every degree of justice; but his name, advice, and opinions are so conspicuous throughout this volume, that I shall be excused for not saying any thing more in the present place, than that he was in his time the best practical surgeon, the best lecturer, the best writer on surgery, the best operator of which this large metropolis could boast.

Another character of still greater genius and originality though of inferior education, was the ever memorable John Hunter, surgeon to St. George's Hospital, who was at once eminent as a surgeon, an anatomist, a physiologist, a naturalist, and a philosopher. Indeed, he was the greatest man that ever adorned the profession, either in ancient or modern times, without making any exception of Hippocrates, the reputed father of physic, Paré, the pride of the French, or Harvey, the still greater glory of England, the immortal discoverer of the circulation of the blood. If Pott materially improved many parts of the practice of surgery in England, and evinced himself to be the most skilful operator of his time, John Hunter was also not less importantly employed in extending the boundaries of physiological knowledge, and in the investigation of human and particularly comparative anatomy. The knowledge which he derived from his favourite studies he constantly applied to the improvement of the art of surgery, and he omitted no opportunity of examining morbid bodies, whereby he collected facts which are invaluable, as they tend to explain the real causes of the symptoms of numerous diseases.

In the practice of surgery, whenever operations proved inadequate to their intention, Mr. Hunter always investigated with uncommon zeal the causes of ill success, and in this way he detected many fallacies as well as made some important discoveries in the healing art. He ascertained the cause of failure common to all the operations in use for the radical cure of the hydrocele, and was enabled to propose a mode of operating attended with invariable success. He ascertained, by experiments and observations, that exposure to atmospherical air, simply, can neither produce nor increase inflammation. He discovered in the blood so many phenomena connected with life, and not to be referred to any other cause, that he considered it alive in its fluid state. He improved the operation for the fistula lachrymalis, by removing a circular piece of the os unguis instead of breaking it down with the point of a trocar. He explained better than any of his predecessors all the highly interesting modern doctrines relative to inflammation, union by the first intention, suppuration, ulceration, and mortification. His writings also throw considerable light on the growth, structure, and diseases of the teeth. As instances of his operative skill, it deserves to be mentioned, that he removed a tumour from the side of the head and neck of a patient at St. George's Hospital, as large as the head to which it was attached; and by bringing the cut edges of the skin together, the whole wound was nearly healed by the first intention. He likewise dissected out of the neck a tumour which one of the best operators in this country had declared, rather too strongly, that no one but a fool or a madman would meddle with; and the patient got perfectly well. But, perhaps, the greatest improvement which he made in the practice of surgery, was his invention of a new mode of performing the operation for the popliteal aneurism, by taking up the femoral artery on the anterior part of the thigh without opening the tumour in the ham.—(See *Trans. of a Society for the Improvement of Med. and Chir. Knowledge.*) The safety and efficacy of this method of operating have now been fully established, and the plan has been extended to all operations for the cure of this formidable disease.—(See *Aneurism.*)

According to Sir Everard Home, Mr. Hunter was also one of the first who taught that the excision of the bitten part was the only sure mode of preventing hydrophobia; and he extended the time during which this proceeding might be reasonably adopted, beyond the period which had been generally specified.

His researches into the nature of the venereal disease, and his observations on the treatment, will for ever be a lasting monument of his wonderful powers of reasoning and investigation. If he left some points of the subject doubtful and unsettled, he has admirably succeeded in the elucidation of others; and his work on this interesting disorder is, with all its defects, the best which is extant.

Even the language and mode of expression of this great man were his own; for so original were his sentiments that they could hardly be delineated by any ordinary arrangement of words. His phrases are still adopted in all the medical schools of this country, and continue to modify the style of almost every professional book. Great as Mr. Hunter's merit as a surgeon was, it was still greater as a comparative anatomist and physiologist. The museum of the Royal College of Surgeons, and his papers in the Phil. Trans., will for ever attest his greatness in these characters.

At the period when the preceding distinguished men upheld the character of their profession in Great Britain, Lancisi, Morgagni, Molinelli, Bertrandi, Guattani, Mascagni, Matani, Troja, and Moscati, were doing the same thing in Italy. Bertrandi's Treatise on the Operations of Surgery, and Troja's work on the Regeneration of Bones, are even at this day works of the highest repute. Of late years, the credit of the Italian surgeons has been honourably maintained, by Monteggia, Scarpa, Paletta, Quadri, Assalini, Morigi, and others. In Holland flourished Albinus, Deventer, Sandifort, and Camper; and in Germany and the north of Europe, the immortal Haller, Heister, well known for his "*Institutiones Chirurgiæ*," Platner, Rœderer (*Elementa Artis Obstetriciæ, Goett.* 1752. *Obs. de Partu Laborioso, decad.* II, 1756), Stein, Bilguer, Acrell, Callisen (*Systema Chirurgiæ Hodiernæ*, 2 *vols.* 8*vo.*), Brambilla, Theden (*Progrès ultérieurs de la Chirurgie*), Schmucker (*Vermischte Chirurgische Schriften, b.* 3, *and Chir. Wahrnehmungen*), Richter (*Traité des Hernies*, 2 *vols.* 8*vo. Bibl. für die Chirurgiæ; Anfangsgr. der Wundarzn.* 7 *b. and Obs. Chirurgicarum Fasc*). Also Arnemann, Weidmann, Beer, Soemmering, Creutzenfeldt, Hesselbach, Hufeland, Gratfe, Klein, Rust, Himly, Langenbeck, Walther, J. A. Schmidt, G. . . Beer, &c. should not be forgotten, several of whom are still pursuing their useful and honourable career. Be it also recorded, as a part of the great merit of the Germans, that they now rank among the best and most minute anatomists; that they are

zealous cultivators of comparative anatomy, that their industry allows no improvement in medical science, wherever made, to escape their notice; and that surgery is greatly indebted to them for the best descriptions of the diseases of the eye.

On the continent the Royal Academy of Surgery at Paris was long considered quite as the solar light of this branch of science. Nothing, indeed, contributed so materially to the improvement of surgical knowledge as this establishment, a noble institution, which, for a long while, gave our neighbours infinite advantage over us, in the cultivation of this most useful profession. The French Revolution, which, by a fatal abuse, involved in the same prohibition both useful and pernicious societies, did not spare even this beneficial establishment, in which emulation and talents had been so long united for the benefit of mankind. The various dissertations published by its illustrious members will serve as a perpetual memorial of the spirit, ability, and success with which its objects were pursued; and centuries hence practitioners will reap from the pages of its memoirs the most valuable information. Although the Academy was deprived of the talents of Louis, who died a short time before its suppression, it yet had at this period several members worthy of continuing its labours, and supporting its reputation: Sabatier, Desault, who may be regarded as the Pott of France, Chopart, Lassus, Peyrilhe, Dubois, Percy, Baudeloque, Pelletan, Sue, &c.

The Academy of Surgery in France was succeeded by what is named the Ecole de Médecine. Desault, who had been almost a stranger in the former, became quite the leading character in the latter. Several things recommended him strongly to the remembrance and admiration of posterity; the exactness and method which he introduced into the study of anatomy; the ingenious kinds of apparatus which he invented for the treatment of fractures; a noble ardour in his profession, which he knew how to impart to all his pupils; his clinical lectures upon surgery, which were the first ever delivered; and the boldness and simplicity of his modes of operating. Indeed, such was his genius, that even when he practised only methods already understood, he did them with so much adroitness, that he rather appeared to be the inventor of them. From the Ecole de Médecine have issued Dupuytren, Boyer, Richerand, Dubois, Lheritier, Manoury, Lallemant, Petit de Lyon, Bichat, Beclard, Cloquet, &c.

Among the public institutions in Europe for the improvement of medical and surgical knowledge, the present Medical and Chirurgical Society of London certainly stands pre-eminent, whether the reputation and number of its members, the importance of many of the papers which it has published, or the extent and value of its library, be taken as the criterion of the character which is here assigned to it. Many of the facts which it has collected and published are of considerable practical importance, especially those relating to the subjects of aneurism, hemorrhage, the diseases of the joints, calculi in the bladder, and that least intelligible of all diseases, syphilis. Its library, which, next to that of the Royal College of Surgeons, is the most select, valuable, and complete collection of medical literature in Great Britain, more especially with reference to modern works, is continually receiving additions, both by large purchases at home and abroad, and by the numerous donations of its members and others. The intercourse and correspondence which such a society always maintains among the innumerable scattered members of the profession, cannot fail to be attended with the most beneficial effects upon medical science in general: a generous and useful sort of emulation is thus kept alive; the spirit of inquiry is kept from slumbering; and every individual who ascertains a new fact has now the means of making it known to the world, with all the expedition which its importance may demand. By this observation I do not mean that it will always appear in print directly after its communication to the society, for that is a circumstance which must necessarily depend upon there being or not a sufficient quantity of interesting matter in the Society's possession to form an additional part to its Transactions; but the very reading of the paper at a public meeting gives it immediate notoriety in the profession, and if its novelty and merit be great, it soon excites very general attention.

The researches of Bichat, who quitted surgery, powerfully contributed to the advancement of physiological science. His mind, richly stored with the positive facts which he had learned in the study of surgery, conceived no less a project than that of rebuilding the whole edifice of medicine. Some courses of lectures upon the materia medica, internal clinical medicine, and morbid anatomy, announced this vast design, which was frustrated by a premature death. Bichat, as a physiologist and man of very original genius, may be considered as the John Hunter of France; but his qualities were of a different cast, and hardly admit of comparison with those of Hunter, whose investigations were not limited to man, but extended to the whole chain of animated beings. Bichat died in the midst of his labours, and, in dying, his greatest regret was that of not having completed them. His example, says Richerand, proves most convincingly what Boerhaave always inculcated, and every man of experience knows how indispensable the study and even the practice of surgery are to him who would wish to be a distinguished and successful physician.—(*Nosogr. Chir. t.* 1, *p.* 25.)

In the course of the last thirty years, great and essential improvements have been made in almost every branch of surgery.

Before the time of Mr. Hunter, our ideas of the venereal disease were surrounded with absurdities; and it is to this luminary and the plain facts laid before the profession by the late Mr. Rose, that we are in an eminent degree indebted for the increased discrimination and reason which now prevail, both in the doctrines and treatment of the complaint. It must be confessed, however, that much yet remains to be made out, respecting the nature and treatment of syphilitic disorders. Need I mention a greater proof of the truth of this remark, than the remarkable change of practice in some of the principal hospitals in London, mercury being now exhibited in not more than one out of eight or ten cases, for which this medicine a few years ago was always deemed indispensable? Numerous cases, having all the characters of primary venereal sores, seem also now to be curable by simple dressings and cleanliness; and the necessity for violent salivation, in any case, begins now to be generally disbelieved. In short, so different is every thing from what it used to be, that many surgeons are tempted to suppose the nature of the venereal disease totally altered.—(See *Venereal Disease.*)

Strictures in the urethra, an equally common and distressing disease, were not well treated of before Mr. Hunter published on the venereal disease. Until his time, we were unacquainted with a good practical method of applying caustic within the urethra, a method which has been still farther perfected with the armed bougies, invented by Sir Everard Home. The latter gentleman indeed, has taken a very scientific view of the whole subject, and perhaps his only error is that of not having sufficiently limited his favourite plan of treatment.

In modern times hernial diseases, those common afflictions in every country, have received highly interesting elucidations from the labours of Pott, Camper, Richter, Sir Astley Cooper, Hey, Gimbernat, Hesselbach, Scarpa, Lawrence, Langenbeck, Cloquet, &c.

The treatment of injuries of the head has been materially improved by Quesnay, Le Dran, Pott, Hill, Desault, Dease, Hey, Abernethy, and Brodie.

The disease of the vertebræ, which occasions paralysis of the limbs, formerly always baffled the practitioner; but the method proposed by Mr. Pott is now frequently productive of considerable relief, and sometimes of a perfect cure. The diseases of the joints in general may also be said to be at present viewed with much more discrimination than they were a very few years ago; and this great step to better and more successful practice reflects great honour on Mr. Brodie, while it keeps up a well-founded hope that morbid anatomy, the study which has of late banished so much confusion from this part of surgery, will yet be the means of bringing to light other useful facts and observations relative to the pathology of the joints.

In the time of Mr. Pott, few patients afflicted with lumbar abscesses ever recovered; for soon after a free opening had been made, according to the method then in vogue, the constitution was usually seized with violent irritative fever, which hardly admitted of any control. Mr. Abernethy ascertained that much of this risk might be avoided by making only a small

opening, healing it by the first intention, after the matter had been let out, and then repeating the same plan from time to time, so as to prevent the cavity of the abscess from ever being distended, and give it the opportunity of diminishing by a natural process. Of course success cannot be expected to attend even this treatment, when the vertebræ are carious, or any other serious organic disease prevails.

The rarely-failing plan of curing hydroceles by means of an injection, as described by Sir James Earle, may be enumerated as one of the most decided improvements in modern surgery: at least no doubt is entertained on this point by any surgeon of eminence in France, the British dominions, or the United States.

[This is the first mention made of the surgeons of the United States in this history of surgery, and it might imply that in this country the radical cure of hydrocele is the very ultimatum of attainment in operative surgery. That the author did not design thus to misrepresent us, is clear from the fact that he hints at Dr. Mott's case of ligature of the innominata, and awards him the meed of originality in amputating the lower jaw, within the two following pages, and also from the respectful notice he has occasionally given to American operations in this Dictionary. In a professed history of operative surgery, however, in which the distinguished men of every other country are named, together with the improvements and benefits they conferred upon science and humanity, one would naturally look for some mention of the names at least of Drs. Physick, White, Dudley, Davidge, Dorsey, Shippen, Bard, Post, Mott, Gibson, Parish, Barton, M'Clellan, Stevens, Warren, Smith, Jamieson, and a host of others who have contributed by the pen and the knife to elevate this department of the profession, and some of them are quite as distinguished in America, as those of whom honourable mention is made justly are, among their transatlantic brethren. This will be admitted, unless the successful ligature of the subclavian, the common iliac, internal iliac, and that of the innominata, the amputation of the hip-joint, and upper and lower jaw, the extirpation of the parotid gland, the exsection of the clavicle, and the cure of aneurism by tying on the distal side of the tumour, be unworthy of record. Some of these operations have never been attempted in Europe until our surgeons led the way, and by these and other splendid achievements in operative surgery demonstrated their practicability and success.

I may be allowed to express the hope that when the author shall favour the profession with a still farther improved edition of his Dictionary so highly appreciated in America, he will provide himself with the materials so accessible, and not again declare without a brief qualification, that "*All* the boldest operations in the treatment of aneurismal diseases have been *devised by the genius*, and executed by the *spirit and skill of British surgeons*." I only here enter a "general plea of demurrer," and shall scatter my "bill of exceptions" throughout my brief notes in the body of the present edition.—*Reese.*]

The increasing aversion to the employment of the gorget in lithotomy, the many distinguished advocates for the use of better instruments, and, above all things, the clearer exposition of the right principles of the operation now made, both by lecturers and authors, I regard as an agreeable indication of the augmented degree of success with which lithotomy is now likely to be practised in every fair case for the operation. The necessity for the same frequent performance of lithotomy which prevailed formerly, must not, however, be now recognised by any humane or judicious surgeon; and I entertain a cheerful hope that the art of pulverizing calculi in the bladder, and voiding the fragments through the urethra, will soon attain such perfection as shall nearly banish the dreadfully painful and frequently fatal practice of cutting into the bladder for the extraction of the stone. The urethral forceps recommended by Sir A. Cooper for removing calculi through the urethra, and all the ingenious inventions of Dr. Civiale, M. Le Roy, and Baron Heurteloup, designed to reduce the stone to powder, so that it may be voided with the urine through the urethra (each plan thus superseding, when it answers, all occasion for lithotomy), are great and signal improvements, which entitle their inventors to a distinguished rank among those men of genius from whose labours the present and future generations will receive inestimable benefit.

The diseases of the eyes, cases to which English surgeons seemed to pay much less attention than was bestowed by foreign practitioners, now obtain due attention in this country. Although we have always had what are called oculists, our regular surgeons have generally been wonderfully ignorant of this part of their profession, and, uninformed on the subject, they have given up to professed oculists and quacks one of the most lucrative and agreeable branches of practice. However, the able writings of Daviel, Wenzel, and Ware begin now to be familiarly known to practitioners; and the observations of Scarpa, Richter, Beer, Schmidt, Himly, Lawrence, Frick, Wardrop, Travers, Saunders, and Guthrie will soon have immense effect in diffusing in the profession a due knowledge of the numerous diseases to which the organs of vision are liable. As likewise the hospital surgeons of London long and grossly neglected the study of these cases, and refused to have any thing to do with them, the public at length saw the necessity of establishing Eye Infirmaries in London and other large towns, where such afflictions might be more attentively observed and relieved. Some of these have now become excellent schools, in which the rising generation of surgeons have abundant opportunities of studying the nature of all the diseases of the eyes, and the most approved methods of treatment.

In the treatment of aneurismal diseases, English surgeons have much to be proud of. All the boldest operations in this branch of surgery have been devised by the genius, and executed by the spirit and skill of British surgeons. Even M. Roux himself is here obliged to confess our superiority.—(*Parallèle de la Chirurgie Angloise, &c. p.* 249.) The carotid artery, the external and internal iliac, and the subclavian have all been successfully tied by surgeons of this country. The first operation in which the external iliac was tied, I was a spectator of: it was performed by Mr. Abernethy in St. Bartholomew's Hospital, and it has subsequently been repeated in many examples, both in this country and others, with considerable success. I had also the honour of seeing the same gentleman tie the carotid, in the first instance of that operation in England. This important measure, which has now been frequently practised with success, constitutes one of the great improvements in the operative part of modern surgery.

In the article Aneurism, I have cited many examples in which the carotid artery has been successfully tied; and the safety and propriety of the operation are now generally known and acknowledged. Indeed, so little are surgeons now afraid of the ill effects upon the brain, that the carotid artery has been tied merely for the purpose of enabling the operator to take away a large tumour, including the whole of the parotid gland, from the side of the neck, without risk of hemorrhage; a mode of proceeding, however, which ought not to be encouraged into a common practice.—(See *Med. Chir. Trans. vol.* 7, *p.* 112.) The example of skill, judgment, and boldness set by the surgeons of this country has not been lost upon foreign practitioners. In France, in Germany, and particularly in the United States of America, operations for aneurism are now familiarly practised. Indeed, in the two latter countries [first in America], the arteria innominata had been tied; a proceeding which, though it was originally suggested here, [?] I believe has not yet been ventured upon in Great Britain: neither may it be now justifiable, since the possibility of curing aneurism on the plan first suggested by Brasdor, and of late most convincingly illustrated by Wardrop, leads to a safer expedient.—(See *Aneurism.*) Mr. Weiss's aneurismal needle, for the conveyance of the ligature under very deep arteries where there is but little room, is also an invention likely to prove of very material service in this branch of surgery, where sometimes the most skilful surgeons have either been quite baffled in their endeavour to pass the ligature under the vessel, or have detained their patient so long in the operating room, exposed to the greatest agony, ere the business was accomplished, that the irritated and reduced state of the constitution seriously lessened the chance of a happy issue. Before I quit this subject, my feelings call upon me to express the high opinion which I entertain of my friend Mr. Hodgson's Treatise on the

Diseases of Arteries and Veins, first published in 1815; a work which reflects great credit on English surgery, and contains practical precepts far superior to those of Scarpa. A new edition of it, enriched with later observations, and the farther experience and reflections of the respected author, I am happy to announce as being on the point of publication.

In the modern practice of surgery, a variety of old prejudices are gradually vanishing. Peruvian bark, not many years ago, was regarded as a sovereign remedy and specific for nearly all cases of gangrene; and in these and many other instances, it was prescribed without any discrimination, and in doses beyond all moderation. But the false idea that this medicine has any specific effect in checking mortification, no longer blinds the senses of the most superficial practitioner. He neither believes this doctrine, nor the still more absurd opinion, that strength can be mysteriously extracted from this vegetable substance, and communicated to the human constitution in proportion to the quantity which can be made to remain in the stomach.

The valuable discoveries recently made in France, relative to quinine and cinchonine, the essential parts of Peruvian bark, comprised in a very small compass, will lead to great amendment in the modes of prescribing this medicine in every case where it may deserve trial.

At the present day, the subject of mortification opens to us a point for investigation of the first rate consequence. Every surgeon is aware that when a limb is deeply affected with mortification, amputation is commonly necessary. This is generally acknowledged; but the performance of the operation has, since the time of Mr. Pott, only been sanctioned when the mortification has manifestly ceased to spread, and a line of separation is formed between the dead and living parts. All other instances in which the disorder was in a spreading state, were left to their fate. It is true, some of the old surgeons occasionally ventured to deviate from this precept; but as they did so without any discrimination or knowledge of the particular examples which ought to form an exception to the general rule, their ill success cannot constitute a just argument against the plan of amputating earlier in a certain description of cases.

Now, if modern experience prove that many lives may be saved by a timely performance of amputation, under circumstances in which it has until lately been generally condemned, it must be allowed that the established innovation will be one of the greatest improvements in the practice of the present time.

For reviving the consideration of this question, and venturing to deviate from the beaten path, the world is much indebted to that eminent military surgeon, Baron Larrey. How different his doctrines and practice are from those usually taught in the schools, the article *Mortification* will sufficiently prove.

Connected with this topic is *Hospital Gangrene*, a case which deserves here to be pointed out, as having received considerable attention of late years, and being much better treated now that the efficacy of the solution of arsenic and strong nitrous acid, has been so completely proved by the observations of Blackadder and Welbank.

In the treatment of ununited fractures, the simple and ingenious practice suggested by Dr. Physick of Philadelphia, merits particular notice: various successful trials have been made of it in this country and France (see *Medico Chir. Trans. vols.* 5 *and* 7; and *Boyer's Traité des Maladies Chir.*) as well as in America, and, though liable to failure, it is yet entitled to be regarded as a valuable addition to the plans hitherto devised for these cases, which too often render the patient a helpless cripple during life.

The inestimable treatise of Dr. Jones on *Hemorrhage* has now produced quite a revolution in all the principles by which the surgeon is guided in the employment of the ligature for the stoppage of bleeding, and the cure of aneurisms. Instead of thick clumsy cords, small firm silks or threads are now generally used; and so far is the practitioner from being fearful of tying arteries too tightly, lest the ligature cut them, that it is now a particular object with him to apply the silk or thread with a certain degree of force, in order that the inner coat of the vessel may be divided. If this be not done, the effusion of coagulating lymph within the artery, an important part of the process of obliteration, cannot be expected as a matter of certainty, and secondary hemorrhage is more likely to occur. But in order to convey an adequate idea of the beneficial changes which Dr. Jones's observations are tending to produce in practice, I have been careful in the article *Hemorrhage*, to give a tolerably full account of the results of all his interesting experiments.

Dr. Veitch, an eminent naval surgeon, deserves here to be also mentioned with particular honour, since he is probably the earliest writer that laid due stress on the advantage of tying the arteries with very small ligatures; one of the greatest improvements in the treatment of wounds and in operative surgery. "My experience and reasoning (says he) led me to recommend a small ligature; and its nature and form were not left to conjecture, but clearly laid down; and the introduction of this practice to surgery is, I think, unquestionably due to me. Dr. Jones did not apply his round ligature to operations on the human body; and the practice of using the small single ligature was not adopted at the Edinburgh Infirmary, in which city his experiments were made until the appearance of the following Essay on the Ligature of Arteries, which was sent to the editor of the Edin. Med. and Surgical Journal in 1805, but was not published until the 1st of April, 1806."—(See *Obs. on the Ligature, &c. Lond.* 1824.) In justice to Dr. Jones I should mention that his book was published in 1805.

Besides using very small, firm, round threads, instead of large, flat tapes or cords, as was the custom a few years ago, some modern surgeons have suspected that much benefit might arise from cutting off both portions of the ligature close to the knot after amputation, the removal of the breast, &c. No one has insisted so much as Mr. Lawrence upon the propriety of examining farther the merits of this innovation. If no bad effects result from leaving so small a particle of extraneous substance in the flesh, as the little bit of silk composing the knot and noose on the artery, the practice will form a considerable improvement. The wound may then be brought together at every point; the quantity of extraneous matter in the part will be lessened to almost nothing; the danger of convulsive affections will be reduced in proportion as a serious cause of pain and irritation is diminished; and the chance of accomplishing perfect union by the first intention will be materially increased. Mr. Lawrence has tried the plan in many instances, and hitherto his experience has not found any ill consequences follow, while it has proved that many advantages are undoubtedly the result of it. Mr. Cross, of Norwich, however, has detailed some observations which are rather against the practice, and it is certainly far from being generally, or even commonly, adopted. After amputation it was practised by several military surgeons in the late war; and although they probably did not employ exactly such ligatures as this mode absolutely requires, few of them met with any instances of future trouble from the minute bits of ligature enclosed in the wound, with the exception of Mr. Guthrie and one or two other army surgeons of my acquaintance. However, if large ligatures be used, the practice is not fairly tried, or rather the practice is not tried at all; because the great principle on which it answers, is the very small atom of silk composing the extraneous substance left in the wound, when such ligatures as Mr. Lawrence particularly recommends are employed. Delpech and Roux have also sometimes adopted the plan of removing the ends of the ligature close to the knot.—(See *Parallèle de la Chir. Angloise avec la Chir. Francoise, p.* 131; See *Amputation, Aneurism, Hemorrhage*, and *Ligature*.

Among other signal improvements in modern practice, I must not forget the present more rational method of dressing the wound, after the majority of capital operations, with light, cooling applications, instead of laying on the part a farrago of irritating pledgets and plasters, and a cumbersome mass of lint, tow, flannel, and other bandages, woollen caps, &c The fewer the adhesive strips are the better, if they only hold the lips of the wound together. This is all they are intended to do. Whereas, if more than are necessary for this purpose be employed, they do harm by heating the part and covering the wound so entirely as to prevent the issue of the discharge. Over the adhesive plasters, let the surgeon be content with placing a simple pledget of spermaceti cerate and some

linen wet with cold water, which will often avert hurtful degrees of pain and inflammation by keeping the parts cool.

Wars, which are unfavourable to most other sciences, are rather conducive to advances in surgery. The many new and interesting observations which Baron Larrey has made in the course of his long and extensive military experience, are a proof of the foregoing remark. Pitard, almost the founder of surgery in France, was a military surgeon. Ambroise Paré and Wiseman collected their most valuable knowledge principally in the service of the army. Mr. Hunter himself gained much of his practical information in the same line of life. To Baron Larrey surgeons are indebted for many highly important observations relating to amputation in cases of gun-shot wounds. In particular, he has adduced a larger and more convincing body of evidence than was ever before collected, to prove that in gun-shot injuries the operation of amputation should always be performed without the least delay, in every instance in which such operation is judged to be unavoidable and the ultimate preservation of the limb either impossible or beyond the scope of all rational probability. He has established the truth of this most important precept in military surgery by innumerable facts, drawn chiefly from his own ample experience, and partly from the practice of many able colleagues. The great operations of the shoulder-joint and hip-joint amputations he has executed with success. The necessity for the former, however, he proves may sometimes be superseded, and the limb be saved, by making a suitable incision for the extraction of the splintered portions of the upper part of the humerus. This method, which was in many instances done with success in the peninsular war, and has been also repeatedly performed with the same result by Baron Percy, was, I believe, originally proposed and practised by Boucher.—(See *Mém. de l'Acad. de Chir. t.* 2, *4to.*) However, it was first more particularly described, and even practised, by Mr. C. White of Manchester.—(See his *Cases in Surgery.*) Mr. Morell also performed it successfully in the York Hospital.—(See *Med. Chir. Trans. vol.* 7.)—See *Amputation.*

Amputation at the hip-joint, performed only in the most dreadful cases, because itself the most dreadful operation in surgery, Baron Larrey has performed five times, and twice (I believe) with success. It has also now been done by Messrs. Brownrigg and Guthrie,* Sir Astley Cooper, Graefe, Walther, Delpech, and others, and several of their cases terminated in the recovery of the patients. As must be the case, however, on account of the desperate circumstances under which the operation is performed, and the severity of the operation itself, the examples of recovery bear only a small proportion to the large number of deaths known to have followed amputation at the hip in the many cases in which it has now been undertaken. Yet this unfortunate truth should not be exaggerated into a reason for an unqualified condemnation of the practice, which is adopted as the only means affording a chance of saving life. But, as there may be difficulty in deciding whether the patient will have the best chance with or without the operation, it is to be hoped that no surgeons will perform it, except under the authority of the united opinion of a board or consultation of the best-informed practitioners, whom circumstances will allow to assemble. It is to be hoped, likewise, that there is no man in the profession so destitute of honour and principle, as to aim at notoriety through the medium of this terrible operation, and court the opportunity of doing it merely with this view, instead of being compelled to undertake it by the really desperate circumstances of the case. If there be such an individual in existence, his scheme of wading through blood to reputation, now that the novelty of the operation has vanished, would have but little chance of success. Be it also recollected by the profession, that while the operation itself requires only ordinary talents, the business of avoiding it, and of discriminating the exact cases in which it should be done, implies an extensive acquaintance with the principles of surgery, ample experience, and more than common abilities and judgment. See *Amputation.*

In military surgery, the useful innovation of *ambulances* or light caravans, furnished with a proper number of surgeons' assistants and orderlies, and capable of keeping up with the vanguard if requisite, is undoubtedly the best means of affording speedy surgical assistance to the wounded on the field of battle, and ought to be enumerated as an arrangement of great consequence in military surgery. Barons Percy and Larrey deserve the chief praise for their successful exertions in organizing and bringing to perfection so indispensable an establishment. The account of this subject well deserves perusal; and it may be seen either in *Larrey's Mémoires de Chirurgie Militaire*, or in the *Dict. des Sciences Médicales*, *t.* 4.

Another improvement in surgery, of an humbler, but not less useful description than some things to which I have already adverted, is the elastic gum seton, which, for cleanliness and convenience, is far superior to what has generally been employed by practitioners. The needle for it and the slips of elastic gum may be procured of Mr. Weiss. The invention, I believe, is one of the results of French ingenuity.

The excision of more or less considerable portions of the lower jaw, in cases of irremediable disease of it, is a new proceeding, exemplifying the still-continued progress of the boldest parts of operative surgery. The practice also merits notice on another account: it is an extension of the most effectual part of surgery to a class of miserable and hopeless cases first devised and executed, I believe, by our transatlantic brethren in the United States, Dr. Mott having been the means of conferring this honour upon them. Indeed, it appears to me that the zeal and talent with which the practice of surgery is now cultivated in that part of the world, will soon render it a frequent source of new and useful suggestions.

The last illustration which I shall quote of the modern advances of surgery, is the discovery of various new active remedies or improved forms of medicine, as iodine, morphine, quinine, and cinchonine. The first, as the most powerful medicine for bronchocele, and for certain chronic enlargements of the breast, testicles, glands, and joints, supposed to be of a scrofulous nature, is a decidedly valuable addition to the surgical pharmacopœia; perhaps the most valuable one that has been made in modern times. With respect to morphine, if experience prove that it possesses all the anodyne qualities of opium without the stimulating ones, in how many cases and circumstances its exhibition may be ventured upon where the practitioner would be fearful of the common preparations of opium! As for quinine and cinchonine, they are considered to possess all the essential qualities of bark; and as the doses are very small, they admit of being prescribed, when the more bulky preparations of it would dangerously disturb both the stomach and bowels.

Let me not conclude this article without offering my sincere congratulations to every lover of surgical science for the impulse which is likely to be given to it by the very liberal and wise regulations lately adopted by the Council of the Royal College of Surgeons in London; regulations which, by annihilating all monopoly in the lecturing department, and acknowledging schools of anatomy and surgery wherever competent ones may present themselves, will give genius and talent fair play, and soon demonstrate that medical science, when properly cultivated, will flourish in many other soils and atmospheres than those of London, Dublin, Edinburgh, Glasgow, and Aberdeen. I also anticipate that in the course of a very short time, we shall see most convincingly exemplified the immortal truths, that the same science will always make the most rapid progress when freed from every unnecessary restriction; and that the larger the field of competition and emulation is for lecturers and hospital surgeons, the more likely are we to see among them men of the first-rate merit. Their reputation, as it ought to do, will ensure to them such a class as will handsomely reward their labour. The public will have the benefit of the valuable doctrines and knowledge imparted by them to their pupils, the rising generation of practitioners to whom must hereafter be confided the arduous and responsible office of administering medical and surgical aid to mankind. As for other teachers of in-

* Dr. Mott performed this operation before Sir Astley Cooper, and with success. See article "Amputation at the Hip-Joint," in this dictionary.—*Reese.*

ferior worth, hitherto kept alive by the artificial support of great hospitals, and pampered by the unjust regulations of colleges, they will quickly find (what is truly desirable) their proper level. If henceforth any principle of monopoly is to be endured in the profession, let it only be such as is the result of that kind of attraction which will forever belong to the charm of genius and the splendour of superior attainments; and may all interference that would lessen the influence of this meritorious principle, meet with eternal resistance and the hatred of every public-spirited man in the profession.

SUSPENSORY. A bandage for supporting the scrotum; a bag-truss. Bandages of this kind are now usually sold at the shops, and seldom made by the surgeons themselves; therefore a particular description of them is not essential in this work. In cases of *hernia humoralis*, varicocele, cirsocele, some particular ruptures, and several affections of the testicle, and spermatic cord, a suspensory bandage is of infinite service.

SUTURES. (From *suo*, to sew.) A mode of uniting the edges of a wound, by keeping them in contact with stitches.

Mr. Sharp remarks, that "when a wound is recent, and the parts of it are divided by a sharp instrument, without any farther violence, and in such manner that they may be made to approach each other, by being returned with the hands, they will, if held in close contact for some time, reunite by inosculation, and cement, like one branch of a tree ingrafted on another. To maintain them in this situation, several sorts of sutures have been invented and formerly practised, but the number of them has of late been very much reduced. Those now chiefly described are the *interrupted*, the *glover's*, the *quilled*, the *twisted*, and the *dry* sutures; but the interrupted and twisted are almost the only useful ones, for the quilled suture is never preferable to the interrupted; the dry suture is ridiculous in terms, since it is only a piece of plaster applied in many different ways to reunite the lips of the wound; and the glover's or uninterrupted stitch, which is recommended in superficial wounds to prevent the deformity of a scar, does rather, by the frequency of stitches, occasion it, and is therefore to be rejected, in favour of a compress and sticking plaster."—(*Oper. of Surgery.*) The twisted suture is described in speaking of the *hare-lip*; and *gastroraphe*, which also properly belongs to the present subject, forms a distinct article in this dictionary.

Interrupted Suture.—The wound being cleansed from all clots of blood, and its lips being brought evenly into contact, the needle, armed with a ligature, is to be carefully carried from without inwards to the bottom, and so on from within outwards. Care must be taken to make the puncture far enough from the edge of the wound, lest the ligature should tear quite through the skin and flesh. This distance, according to Mr. Sharp, may be three or four-tenths of an inch. The other stitches required are only repetitions of the same process. The threads having been all passed, "you are in general to begin in tying them in the middle of the wound; though, if the lips be held carefully together, it will not be of great consequence which stitch is tied first."—(*Operations, chap.* I.)

Surgical writers in general state, that the number of stitches must in a great measure depend upon the extent of the wound. The common rule is, that one suture is sufficient for every inch of the wound; but that in some instances a stitch must be more frequently made, particularly when a wound gapes very much, in consequence of a transverse division of muscles. As we have already explained, it is necessary to pierce the skin at a sufficient distance from the sides of the wound, lest the thread should cut through the flesh in a short time: but though Mr. Sharp lays down the necessary distance in general, as three or four-tenths of an inch, and others advise the needle to be always carried through the deepest part of the wound, we must receive these directions, particularly the last, as subject to numerous exceptions. When a wound is very deep, it would be conspicuously absurd, and even, in many instances dangerous, to drive the needle through a vast thickness of parts. Other wounds of considerable length might not be, in some places, four tenths of an inch deep; though it is true, sutures could never be requisite at such points.

The needles for making the interrupted suture will pass with the greatest facility when their shape corresponds exactly with the segment of a circle, and they should always form a track of sufficient size to allow the ligatures, which they draw after them, to pass through the flesh with the utmost ease.

The interrupted suture obviously receives its name from the interspaces between the stitches: and it is the one most frequently employed. Its action is always to be assisted and supported, either with the uniting bandage (see *Bandage*), or with strips of adhesive plaster, compresses, &c.

Quilled Suture. As Mr. John Bell has observed: "When the wound was deep among the muscular flesh, the old surgeons imagined, that so large a wound could not be commanded by the common interrupted suture, however deep the stitches might be driven among the flesh; they were, besides, fearful of using the continued (glover's) suture in deep gashes, lest the wound should be made to adhere superficially while it was still open within, forming perhaps a suppuration or deep collection of matter. They believed, that a deep muscular wound could not be safely healed without a degree of suppuration: while they wished to bring it together at the bottom, they were afraid to close it very exactly at the mouth, lest the matter should be collected in the deeper parts of the wound: it was for this purpose (says Mr. John Bell) that they used what they called the *compound* or *quilled suture* It is merely the interrupted suture, with this difference, that the ligatures are not tied over the face of the wound, but over two quills or rolls of plaster, or bougies, which are laid along the sides of the wound. In performing this suture, we make first two, three, or four stitches of the interrupted suture very deep, and then, all the ligatures being put in, we lay two bougies along the sides of the wound; then slip one bougie into the loop of the ligatures on one side, drawing all the ligatures from the other side (Mr. Bell should rather have said towards the other side), till that bougie is firmly braced down. Next we lay the other bougie, and make the knots of each ligature over it, and draw it also pretty firm; and thus the ligatures, in form of an arch, go deep into the bottom of the wound, and hold it close, while the bougies or quills keep the middle of the wound, and lips of it, pressed together with moderate closeness, and prevent any strain upon the threads, or any coarse and painful tying across the face of the wound." In a note, Mr. J. Bell says that Dionis violently reprobates the quilled suture; but that De la Faye (the annotator on Dionis) says, it is good for deep muscular wounds. The quilled suture is now scarcely ever employed; nor has it any advantages, except, perhaps, in some wounds in the belly.—(See *Principles of Surgery, vol.* 1, *p.* 50.)

I think the reader will more easily comprehend the manner of making the quilled suture, from the following simple directions. Take as many needles as stitches intended to be made, arm them with a double ligature, or one capable of being readily split into two, introduce the ligatures through the wound, cut off the needles, lay a piece of bougie along one side of the wound, and tie the ends of the ligatures over it. Next draw the other extremities of the ligatures, so as to bring the first piece of bougie into close contact with the flesh; lay the second piece of bougie along the opposite side of the wound, and tie the other ends of the ligatures over it with sufficient tightness.

Glover's Suture. This had also the name of the continued suture. It was executed by introducing the needle first into one lip of the wound, from within outwards, then into the other in the same way; and in this manner the whole track of the wound was sewed up.

The glover's suture has long been rejected by all good surgeons, as improper to be employed in cases of common wounds. It was not, however, till very lately that this suture was totally abandoned; for Mr. Sharp, and several eminent writers since his time, have advised its adoption in wounds of the stomach and intestines. From what has been said in the articles *Wounds of the Abdomen* and *Hernia*, the reader will perceive, that even in such particular instances the glover's suture would not be advisable: so that it may, in every point of view, be now considered as totally disused in every case of surgery which can possibly present itself. When we remember in making this suture, how many

stitches are unavoidable; how unevenly, and in what a puckered state, the suture drags the edges of the skin together; and what irritation it must produce; we can no longer be surprised at its now being never practised on the living subject. It is commonly employed for sewing up dead bodies; a purpose for which it is well-fitted; but for the honour of surgery, and the sake of mankind, it is to be hoped that it will never again be adopted in practice.

False or *Dry Suture.* Modern surgeons commonly understand, by this expression, nothing more than the plan of bringing the sides of a wound together by means of adhesive plaster; nor did Mr. Sharp attach any other meaning to the phrase, which he sets down as highly ridiculous, as there is no sewing employed. For the following remarks I am indebted to Mr. Carwardine, of Earls Colne Priory, near Halsted, Essex. Alluding to what was stated in the third edition of this dictionary concerning the dry suture, he observes, "You do not appear to be aware, any more than Mr. Sharp, of the precise mode of its application, or why it was so called. Indeed, it is a curious circumstance how this method of dry suture should have been so lost as not to be described by any modern surgeons, who laugh at the very term, speaking of it as a mere application of a strip of adhesive plaster. In the *sutura sicca*, so called in opposition to the *sutura cruenta*, where blood followed the needle, some adhesive plaster was spread on linen having a selvage. A piece of this was applied along each side of the wound (the selvages being opposed to each other), and then drawn together by sewing them with a common needle, without bloodshed. Hence the term *sutura sicca.* The dry suture was used in all wounds of the face, to avoid scars. You will find it thus described by our countryman Thomas Gale, in his Enchiridion, 1563; and also by A. Paré, who gives a figure of it in his folio work, 1579." I feel much obliged to my friend Mr. Carwardine for this explanation, without which the expression *dry suture* is undoubtedly absurd. As the common way of dressing wounds with sticking-plaster will come under consideration in a future part of this work (see *Wounds*), I shall not here detain the reader upon that topic.

Sutures, by which I mean such as were made in the flesh with a needle and ligature, were much more frequently employed by the old surgeons than they are by the moderns. The best practitioners of the present day never resort to this method of holding the sides of a wound in contact, except in cases in which there is a real necessity for it, and other modes will not suffice.

There were, indeed, certain instances in which the employment of sutures was long ago forbidden. Of this kind were envenomed wounds, in which accidents the destruction of the poison always formed a principal indication in the treatment. Wounds, accompanied with considerable inflammation, were not deemed proper for the use of sutures, as the stitches had a tendency to increase the inflammatory symptoms. Also, as contused wounds necessarily suppurated, and consequently could not be united, sutures were not recommended for them; nor were they judged expedient for wounds attended with such a loss of substance as prevented their lips from being placed in contact. Formerly, wounds penetrating the chest were not united by sutures; nor were those in which large blood-vessels were injured; at least until all danger of hemorrhage was obviated by the vessels being tied.

Dionis believed, with several other authors, that wounds should not be united when bones were exposed, on account of the exfoliations which might be expected. This precept is no longer valid; for when bones are neither altered nor diseased, and are only simply denuded or divided with a cutting instrument, no exfoliations will commonly follow, if the surgeon take care to replace the fresh-cut soft parts, so as to cover the exposed portion of the bone. The practicableness of uniting wounds attended with the division of a bone, is confirmed by numerous facts. De la Peyronie communicated to the French Academy of Surgery a case conclusive on this point. A man was wounded with a cutting instrument, in an oblique direction, on the external and middle part of the arm. The bone was completely cut through, together with the integuments and muscles, in such a manner that the arm only hung by an undivided portion of the skin, about an inch wide, under which were the large vessels. De la Peyronie tried to unite the parts, being convinced that it would be time enough to amputate afterward, if the case should require it. He placed the two extremities of the divided bone in their natural situation, made several sutures for promoting the union of the soft parts, and applied a bandage to the fracture. In this bandage there were slits or apertures over the wound, to allow the dressings to be applied. Spirit of wine, containing a little muriate of ammonia, was used as a topical application; and the fore-arm and hand, which were cold, livid, and insensible, were also fomented with the same. By these means, the natural warmth was restored, and the wound was dressed. In a week, the dressings were removed through the opening in the bandage; in a fortnight they were changed a second time, and the wound seemed disposed to heal. On the eighteenth day, the healing had made considerable progress; the part had a natural appearance; and the beating of the pulse was very perceptible. De la Peyronie now substituted a common roller for the preceding bandage, and care was taken to change the dressings every ten days. In about seven weeks all applications were left off, and at the end of two months the patient was quite well, with the exception of a little numbness in the part. This case is one of the most important in all the records of surgery; for it displays, in a most striking manner, what very bad wounds it is the duty of the surgeon to attempt to unite: and, above all, it exemplifies the propriety of attempting to save many compound fractures, which, judged of only from first appearances, would lead almost any one to resort to amputation. In such cases, when the divided parts are put in contact, the appearances are quite altered.

From what has been already stated, it appears that surgeons, a considerable time back, did not at once sew up every sort of wound; though the considerations which led them not to close the wound were erroneous, as may perhaps be said with respect to the apprehension of bleeding and exfoliations. The best modern practitioners employ sutures much less frequently than their predecessors. Pibrac's dissertation on the abuse of sutures, inserted in the third volume of the Memoirs of the Academy of Surgery, has had considerable effect in producing this change, and I may safely add, this improvement in practice. That judicious and enlightened practitioner opposed the method of uniting wounds by means of sutures, which he contended ought never to be adopted in practice, except in certain cases, in which it was absolutely impossible to keep the sides of the wound in contact, by means of a suitable posture, and the aid of a methodical bandage. Such circumstances Pibrac represents as exceedingly rare, if they ever occur at all. He speaks of sutures as seldom fulfilling the intention of the surgeon, who, in the majority of cases in which he employs them, finds himself necessitated to remove them, before they have accomplished the wished-for end. Pibrac believes that sutures are generally more hurtful than conducive to the union of wounds; and that when they succeed, they do not effect a cure more speedily than a proper bandage. He cites numerous cases of very extensive wounds of the abdomen, neck, &c. for the cure of which a bandage proved effectual, and this even in many instances in which sutures had previously failed, and cut their way through the flesh. Louis, who adopted the opinions of Pibrac, published, in the fourth volume of *Mém. de l'Acad. Chirurgie*, a valuable dissertation, in which he endeavours to prove, that even the hare-lip can be better united by means of the uniting bandage than with sutures; a case, however, which the best modern surgeons very rightly agree to consider, for particular reasons, elsewhere noticed (see *Hare-lip*), as an example in which a suture is advisable.

As far as I can judge, the fair statement of the matter is, that sutures are by no means requisite in the generality of wounds; but that there are particular cases in which either their greater convenience or superior efficacy still makes them approved. Since they cannot be practised without additional wounds being made, and pain occasioned, and since the threads always act as extraneous bodies in the parts, exciting more or less inflammation and suppuration round them; there can be no doubt that their employment is invariably wrong, whenever the sides of a wound can

be maintained in contact by less irritating means with equal steadiness and security. For what is it which generally counteracts the wishes of the surgeon, and renders his attempts to make the opposite surfaces of wounds grow together unavailing? Is not the general cause too high a degree of inflammation, which necessarily ends in suppuration? Are not sutures likely to augment inflammation, both by the additional wounds of the needles, and the still more pernicious irritation of the threads, which always act as foreign bodies, sometimes producing not merely an increase of inflammation and suppuration in their track, but frequently ulceration or sloughing of the parts; and in particular constitutions an extensive erysipelatous redness.

In consequence of the ulcerative process, sutures very often cease to have the power of any longer keeping the edges of wounds in contact; as the observations of Pibrac, and, indeed, what every man may daily remark in practice, fully testify: and the violent inflammatory symptoms which are excited frequently oblige the surgeon to cut the threads and withdraw them altogether.

But even admitting, that, by the general adoption of sutures, some wounds would be united which could not be so were this means abandoned, still it must be allowed, on the other hand, that the cause of other wounds not uniting is entirely ascribable to the irritation occasioned by the sutures themselves. Hence, if it be only computed, that as many wounds are prevented from uniting by the irritation of sutures, as other wounds which are united by their means, and could be united by no other methods, we must still perceive, that mankind would be no sufferers, and surgery undergo no deterioration, were sutures altogether rejected from practice. I believe, however, that every man who has had opportunities of observation, and has made use of them with an unprejudiced mind, will feel persuaded, that more wounds are hindered from uniting by sutures, than such as are healed by them, and *could not be united by other means*.

But prudent practitioners are not obliged either to condemn or praise the use of sutures in every instance without exception. Men of independent principles will always adopt the line of conduct which truth points out to them as that which is right; nor will they obstinately join Pibrac and Louis, in contending that sutures are always improper and disadvantageous, nor imitate other bigoted persons who may use sutures in every kind of wound whatever. Perhaps sutures are still rather too much employed, and, in all probability, will long be so. It will be difficult entirely to eradicate the prejudices on which their too frequent use is founded, as long as what may be called the teachers of surgery are seen holding up the practice for imitation in every principal hospital in the kingdom. Such surgeons, however, as are ready to imbibe fair and candid sentiments on the subject, and to qualify themselves for practising this part of surgery with judgment, should by no means neglect to read what Pibrac and Louis have written on the subject. I know that the latter authors are a little too sanguine in their representations; but as I have already remarked, sutures are still rather too much used, and something is yet necessary for the abolition of a certain unwarranted habit of having recourse to them without real necessity. Nothing will tend to produce this desirable change so much as the perusal of every argument against their employment.

I am decidedly of opinion, not only from what I have read, but what I have actually seen, that the sides of the generality of wounds are capable of being effectually kept in contact, by means of a proper position of the part, and the aid of strips of adhesive plaster, compresses, and a bandage. I believe that such success can be obtained with every advantage which can be urged in favour of sutures and without their disadvantages; such as greater pain, inflammation, &c. I even think, with Louis, that the hare-lip might in general be united very well by means of a bandage; but still I am of opinion, that the twisted suture is attended with least trouble, is most suited for universal practice, and that unless such pains were taken as many practitioners would not, and others could never take, the method by bandage would frequently fail.

I find it exceedingly difficult to lay down any fixed principles for the guidance of the surgeon, in respect to when he ought and when he ought not to use sutures.

Perhaps sutures should be made use of for all cuts and wounds which occur in parts of the body subject to an unusual degree of motion, such as would be apt to derange the operation of bandages, sticking-plaster, and compresses. Hence, the propriety of using the twisted suture for the hare-lip.

Sutures are probably, for the most part, advantageous in all wounds of the abdomen, of a certain length, and attended with hazard of the viscera making a protrusion. In this situation the continual motion and action of the abdominal muscles in respiration, besides the tendency of the viscera to protrude, may be a reason in favour of the use of sutures.

When two fresh-cut surfaces positively cannot be brought into contact by sticking plaster, bandages, the observance of a proper posture, &c., there can be no doubt of the advantages of using sutures, if they will answer the purpose. Some wounds of the trachea, some wounds made for the cure of certain fistulous communications between the vagina and bladder, or others for the cure of similar affections in the perinæum, afford instances of cases to which I allude.

I observe that many surgeons in this metropolis use sutures for bringing the sides of the wound together after several operations; as that of removing a diseased breast, castration, and operations for strangulated hernia.

The reason for using sutures in the scrotum, I suppose, arises from the difficulty of keeping the edges of the wound in contact, owing to the great quantity and looseness of the part. In this case, I will not presume to say that sutures may not sometimes be really necessary, though in general it is best to dispense with them; but after the amputation of the breast, I have no hesitation in pronouncing their employment to be always wrong and injudicious.

I shall conclude with referring to what Pibrac and Louis have written on the above subjects, in *Mém. de l'Acad. de Chir. t. 3 and 4. Sharp, Dionis, Gooch, Le Dran, Bertrandi, Sabatier, B. Bell, and J. Bell, have all treated of sutures.* See also *C. E. Boecler, Suturæ Vulnerum; Upsal*, 1772.

SYMPATHETIC BUBO. See *Bubo.*

SYNCHYSIS. (From *συγχύω*, to confound.) The term *synchysis* sometimes denotes the confusion of the humours of the eye, occasioned by blows, and attended with a rupture of the internal membranes and capsules. Beer understands by the expression a dissolution of the vitreous humour, or the state of it in which its consistence is entirely destroyed.—(See *Lehre von den Augenkr. b. 2, p.* 257.)

SYNECHIA. The case in which the iris adheres to the cornea is termed *synechia anterior;* that in which the uvea adheres to the capsule of the lens, *synechia posterior.* Beer has delivered two valuable chapters on these subjects. The synechia posterior, on account of the frequent delicacy of the adhesions, is apt not to be detected, unless the eye be examined with particular care. A magnifying glass should be used, and the pupil be first dilated with hyoscyamus or belladonna. The treatment, as far as the prevention and removal of such adhesions are practicable, strictly belongs to the subject of iritis.—(See *Ophthalmy.*) With the view of dispersing them, Beer praises the good effects of applying to the eye itself ointments containing preparations of mercury, or a collyrium hydrargyri oxymuriatis, to which some of the thebaic tincture is added. As an inward medicine, he says, calomel is the most effectual. When eye-salves are used, Beer recommends a little of the extract of hyoscyamus to be mixed with them, so that they may dilate the pupil, and thus suddenly break any slight threads of lymph.—(*B. 2, p.* 58.) For additional information on the synechia posterior and anterior, see *Lehre von den Augenkr. b. 2, p.* 54, and *p.* 263. Also *Beger, De Synechia, seu preternaturali Adhesione Corneæ cum Iride. Haller, Disp. Chir. t.* 1, *p.* 435.

SYNTHESIS. (From *σὺν*, together, and *θέσις*, position, situation.) A generic term, formerly used in the schools of surgery, and comprehending every operation by which parts that had been divided were reunited.

SYPHILIS. Lues Venerea. The venereal disease.—(See *Venereal Disease.*)

T

T BANDAGE. A bandage, so named from its figure. It is principally used for supporting the dressings after the operation for the cure of fistula in ano, in diseases of the perinæum, and those of the groin, anus, &c. It is composed of two longitudinal pieces of cloth, of greater or less breadth, according to circumstances. The transverse piece of cloth serves to go round the body above the hips; the perpendicular piece is sewed at one of its ends to the middle of the latter; and, in general, its other extremity is slit into two portions or tails, about six or eight inches long. The perpendicular piece of the T bandage applies itself between the glutæi muscles, and to the perinæum; while its two ends, just described, are to be carried between the thighs and the pudenda to the right and left, and fastened to the transverse piece surrounding the body. Besides the common T bandage, there is another one named *double*, which has two perpendicular pieces sewed to the transverse one, about four inches apart. The double T bandage is said to be more particularly applicable after lithotomy, and for the diseases of the perinæum; because one may make the two perpendicular pieces cross each other on the part affected, and leave the anus uncovered; an advantage which the simple T bandage certainly has not. The T bandage may be used in some other ways, which have been noticed in the article *Bandage*.

TALPA. (A mole.) A tumour under the skin, compared to a mole under the ground. Such is the etymology. Sometimes it means an encysted tumour on the head.—(See *Atheroma*, and *Tumours, Encysted*.)

TAPPING. See *Paracentesis*.

TARAXIS. (From ταράσσω, to disturb.) A slight inflammation of the eye.

TAXIS. (From τάσσω, to put in order.) The operation of reducing a hernia with the hand.—(See *Hernia*.)

TENDONS, RUPTURE OF. The tendons liable to be broken by the violent action of the muscles with which they are connected, are the tendo achillis, that of the extensor muscles of the leg, and the tendon of the triceps extensor cubiti. The ancient surgeons seem not to have been well acquainted with the rupture of the tendo achillis, which they probably might mistake for a sprain, or some other complaint. In cases in which this part had been cut, they recommended approximating the separated portions, and maintaining them in contact by means of a suture.

When the ruptured tendo achillis was afterward better understood, the plan just mentioned was even adopted in this case, the integuments having been previously divided, for the purpose of bringing the tendon into view. But there is no necessity for having recourse to this painful proceeding.—(*Encyclopédie Méthodique, partie Chir. t. 1, p. 55.*)

The superficial situation of the tendo achillis always renders the diagnosis of its rupture exceedingly obvious; and the accident can only become at all difficult to detect, when there is a considerable degree of swelling, which is very rare. When the tendon has been cut, the division of the skin even allows the accident to be seen. When it has been ruptured, the patient hears a sound, like that of the smack of a whip, at the moment of the occurrence. In whatever way it has been divided, there is a sudden incapacity, or at least an extreme difficulty either of standing or walking. Hence the patient falls down, and cannot get up again. Besides these symptoms, there is a very palpable depression between the ends of the tendon, which depression is increased when the foot is bent; and diminished, or even quite removed, when the foot is extended.

The patient can spontaneously bend his foot, none of the flexor muscles being interested. The power of extending the foot also is still possible, as the peronæi muscles, the tibialis posticus, and long flexors of the toes (see *a case reported by J. L. Petit*) remain perfect, and may perform this motion.—(*Œuvres Chir. de Desault, par Bichat, p. 1.*)

The indications are, to bring the ends of the divided part together, and to keep them so, until they have become firmly united. The first object is easily fulfilled, by putting the foot in a state of complete extension; the second, namely, that of keeping the ends of the tendon in contact, is more difficult.

In order to have a right comprehension of the indications, we should consider what keeps the ends of the tendon from being in contact. The flexion of the foot has this effect on the lower portion; the contraction of the gastrocnemius and solæus on the upper one. The indications then are, to put the foot in an unalterable state of extension, and to counteract the action of the above muscles.

The action of the muscles may be opposed:—1. By keeping these powers in a continual state of relaxation. For this purpose, the leg must be kept half-bent upon the thigh. 2. By applying methodical pressure to the muscles; methodical, because it is to operate on the fleshy portion of the muscles, and not on the tendon, the ends of which being depressed by it, would be separated from each other, and instead of growing together, would unite to the adjacent parts. The pressure should also operate so as to prevent the ends of the tendon from inclining either to the right or left.

J. L. Petit seems entitled to the honour of having first devised the plan of treating the ruptured or divided tendo achillis, by keeping the leg and foot in a particular posture, with the aid of an apparatus. Seeing that the extension of the foot brought the ends of the tendon into contact, it occurred to him that such extension should be maintained during the whole of the treatment, in order to bring about a permanent union. This aim is, in fact, the common basis of all the numerous methods of cure which have been since recommended.

Dr. Alexander Monro, primus, happened to rupture his tendo achillis. When the accident took place, he heard a loud crack, as if he had suddenly broken a nut with his heel, and he experienced a sensation as if the heel of his shoe had made a hole in the floor. This sensation, he says, has also been observed by others, though some have complained of a smart stroke, like what would be produced by a stone or cane. Immediately suspecting what had happened, the doctor extended his left foot, in which the occurrence had taken place, as strongly as he could with his right hand, while with the left he pressed the muscles of the calf downwards, so as to bring the ends of the broken tendon as near together as possible. In this position he sat until two surgeons came to his assistance. They applied compresses, and a bent board to the upper part of the foot and fore part of the leg, both which they kept as nearly as possible in a straight line, by a tight bandage made with a long roller. But as this mode of dressing soon became very uneasy, it was changed for the following one. A foot-sock, or slipper, was made of double-quilted ticking, from the heel of which a belt or strap projected, of sufficient length to reach over the calf of the leg. A strong piece of the same materials was prepared of sufficient breadth to surround the calf, and this was fastened with lacings. On the back part of this was a buckle, through which the strap of the foot-sock was passed, so that the foot could be extended, and the calf brought down at pleasure. The leg and foot were wrapped up in soft flannel, fumigated with benzoin, and the bandage was kept on day and night, the belt being made tighter when the doctor was about to go to sleep, and loosened when he was awake and on his guard. For a fortnight he did not move his foot and leg at all, but was conveyed in a chair on castors from one part of the room to another. After this, he began to move the ankle-joint, but in such a gentle manner as not to give any pain. The degree of motion was gradually increased, as the tendon became capable of bearing it, care being taken to stop when the motion began to create uneasiness. The affected limb was moved in this way for half an hour at a time. In a few days the hollow between the separated ends of the tendon became imperceptible, though the part continued soft much longer. It became, however, gradually thicker and

harder, until a knot was at last formed in it, apparently of a cartilaginous nature. Though this was at first as large as a middling plum, and gradually became softer and smaller, yet it did not disappear entirely. Having occasion to go out six weeks after the accident, the doctor put on a pair of shoes with heels two inches high, and contrived a steel machine to keep his foot in the proper position. This machine, however, he afterward changed for another, made of the same materials as the former. It was not till five months after the accident, that he thought proper to lay aside all assistance, and to put the strength of the tendon to a trial.—(See *Monro's Works*, *p.* 661.)

Both in a wound and rupture of the tendo achillis, the ancient method of using a suture for keeping the ends of the tendon in contact, is at present quite exploded, and position of the limb is the grand agent by which the cure is now universally accomplished. The following was Desault's method, which, though it was expressly designed to fill all the above-mentioned indications, may not be a more valuable practical plan than what was adopted by Dr. Monro. After the ends of the tendon had been brought into contact, by moderate flexion of the knee and complete extension of the foot, Desault used to fill up the hollows on each side of the tendon, with soft lint and compresses. The roller applied to the limb made as much pressure on these compresses as on the tendon; and hence this part could not be depressed too much against the subjacent parts. Desault next took a compress, about two inches broad, and long enough to reach from the toes to the middle of the thigh, and placed it under the foot, over the back of the leg and lower part of the thigh. He then began to apply a few circles of a roller round the end of the foot, so as to fix the lower extremity of the longitudinal compress. After covering the whole foot with the roller, he used to make the bandage describe the figure of 8, passing it under the foot, and across the place where the tendon was ruptured; and the method was finished by encircling the limb upwards, with the roller, as far as the upper end of the longitudinal compress.—(See *Monro's Works. Encyclopédie Méthodique, article Achille, Tendon de;* and *Mémoire sur la Division du Tendon d'Achille, in Œuvres Chir. de Desault, par Bichat, t.* 1, *p.* 306.)

A rupture of the tendon of the extensor muscles of the leg would require nearly the same kind of treatment as a fracture of the patella. However, pressure exactly on the broken part of the tendon should be avoided; the limb should be kept extended, and somewhat raised; a bandage might be put round the thigh, and antiphlogistic treatment be at first adopted. In the course of two or three weeks, the surgeon should cause the joint to be very gently moved, without any muscular exertion on the part of the patient himself. When the tendon of the triceps extensor cubiti is ruptured, the limb is to be kept straight; cold applications are to be used for a few days; and, if necessary, strict antiphlogistic treatment pursued.

TENT. A roll of lint for dilating openings, sinuses, &c.

TEREBELLA. (Dim. of *terebra*, a perforating instrument.) A trepan, or instrument for sawing out circular portions of the skull. A trephine.

TEREBRA. (From τρέω, to bore.) A trepan, or trephine. Also an instrument called a perforator.

TESTICLE, DISEASES OF. For an account of many of these affections, I must refer to distinct articles in this Dictionary; for instance, *Cirsocele, Fungus Hæmatodes, Hernia Humoralis, Hæmatocele, Hydrocele, &c.*

Mr. Pott defines *sarcocele* to be a disease of the body of the testicle, and as the term implies, it consists, in general, in such an alteration made in the structure of that organ as produces a resemblance to a hard, fleshy substance, instead of that fine, soft, vascular texture which it naturally presents. "*Sarcocele* (says Callisen) is a name applied to every chronic swelling of the testicle, attended with a total or partial conversion of the part into a heterogeneous substance."—(*Systema Chirurgiæ Hodiernæ, pars* 2. *p.* 144.) According to these definitions, sarcocele becomes a term admitting of almost general application to morbid affections of the testicle, since most of them are attended with induration and swelling of the part. In fact, we find that the old writers, and a great many of the moderns, call all diseased indurations and enlargements of the testicle *sarcoceles*, whether the disorder be a simple, chronic, indolent tumour, unaccompanied with any symptoms of specific disease or malignancy, or whether it be a scrofulous, or what is still more different and more serious, a truly scirrhous disorder of the organ. Even the fungus hæmatodes of the testicle was, until lately, often termed sarcocele.

That this vague method of employing the word sarcocele can be attended with no advantage, but on the contrary must have a tendency to destroy all useful discrimination, is a proposition the truth of which is self-evident. I am well aware that Mr. Pott, and many late writers, set out with an idea that every sarcocele has a propensity to change into scirrhus, and actual carcinoma, and therefore the latter states are considered by these authors only as stages of the same disease. Indeed, it is mostly believed that a common indolent sarcocele, a simple fleshy enlargement of the testicle, may change into the peculiar malignant disease called scirrhus, or cancer. But yet it is by no means proved, that all the diseases which are comprehended under the name of sarcocele, are accompanied with a risk of their assuming the nature of scirrhus and cancer; for nothing can be more certain, than that the enlargement of the testicle, produced by fungus hæmatodes, is from the first to the last always of one character, and can never change into ordinary scirrhus or carcinoma. Neither do indolent scrofulous swellings of this organ ever undergo such an alteration as deserves the epithets of *scirrhous* and *cancerous*. In opposition to the belief of Mr. Hunter (see *his Treatise on the Venereal Disease, p.* 59), some surgeons still imagine, that there is really one kind of chronic enlargement of the testicle arising from a venereal cause. —(*Roux, Parallèle de la Chirurgie Anglaise, &c. p.* 305. *Richerand, Nosographie Chir. t.* 4, *p.* 300, *edit.* 4.) Now this also has usually been called a sarcocele; it was so named by Pott himself; and if there be such a case, no one will suppose that it, or any other form of lues venerea, is capable of changing into a true scirrhous or cancerous disease. Perhaps, therefore, it might be more consistent and advantageous to restrict the appellation of *sarcocele* to an indolent fleshy enlargement of the testicle, unaccompanied with any present symptoms of malignancy, or any marks of its being the effect of a specific disease; and as soon as the case evinces another character, the name should correspond with the particular nature of the disease.

We need not here enter into a minute account of the various sarcomatous diseases, to which the testicle is subject; for they have no peculiarity in them, except what depends upon their situation; and the general characters of the different species of sarcoma will be considered in a future article.—(See *Tumour.*) The testicle is especially liable to three kinds of sarcoma, which have been named by Mr. Abernethy, the *common vascular*, the *cystic*, and the *medullary*. The latter case, which used to be called *soft cancer of the testicle*, is described in this work under the name of *Fungus Hæmatodes*. Sometimes the testicle is converted into a truly *scrofulous* mass. It is increased in size, and, when cut into, a whitish or yellowish coagulated matter is discovered, mixed with pus. The complaint is not attended with so much pain and induration as a scirrhous disorder of the testicle; nor does it produce any unfavourable state of the health.

As Dr. Baillie observes, the testicle is often found converted into a hard mass of a brownish colour, and generally intersected with membranes. Sometimes there are cells in the tumour, which are filled with a sanious fluid.—(*Morbid Anatomy, &c. p.* 352. 353, *edit.* 2.) This is the truly *scirrhous testicle*, which is attended with great hardness, severe pains darting along the spermatic cord to the loins, and an unequal knotty feel. In general, the health becomes impaired. To use Mr. Pott's words, sometimes the fury of the disease brooks no restraint; but making its way through all the membranes which envelope the testicle, it either produces a large, foul, stinking, phagedenic ulcer, with hard edges, or it thrusts forth a painful gleeting fungus, subject to frequent hemorrhage.—(*Pott's Chirurgical Works, vol.* 2, *p.* 390, *edit.* 1808.) These latter states of the disease are denominated *cancer of the testicle*.

Sooner or later, the scirrhous induration extends from the epididymis upwards along the spermatic cord, even within the abdominal ring. In the latter circum-

stance, the lymphatic glands in the groin usually become diseased; and this extension of mischief, together with the impossibility of removing the whole of the diseased cord, too frequently deprives the patient of every chance of getting well.

I have already stated, that some of the most simple sarcomatous enlargements of the testicle are capable of assuming, in a very sudden manner, a malignant and cancerous tendency; and that sometimes the scirrhous induration of the cord makes a rapid progress upwards. Hence, that surgeon acts with prudence who recommends the early extirpation of every testicle which is incurably diseased, and so deprived of its original organization as to be totally unfit for the secretion of the semen.

Chronic enlargements of the testicle are sometimes attended with an accumulation of limpid fluid in the tunica vaginalis, and the disease is then termed *hydrosarcocele*, an appellation first employed by Fabricius ab Aquapendente.

The hardness and swelling of the epididymis, remaining after an acute inflammation of the testicle (see *Hernia Humoralis*) do not constitute a complaint which surgical authors class with sarcocele; for the disease hardly ever increases so as to give trouble.

[As it is obvious that Mr. Cooper intended to say something of the nature and treatment of hernia humoralis, but has omitted it both here and in the article itself, I have determined to supply the omission in this place.

This term, hernia humoralis, is applied to that species of swelled testicle which arises sympathetically upon any considerable irritation in the urethra, whether excited by strictures, injections, bougies, or the specific inflammation of gonorrhœa. The generic name now given to it by modern surgical writers is orchitis, from ὄρχις, a testicle, and which is certainly preferable, as possessing the true character of a definition, according to the present nomenclature.

Orchitis is characterized by a painful swelling and inflammation of the testis and epididymis. It is sudden in its attack, and as suddenly disappears under the appropriate treatment. It is sometimes very violent in its onset, and speedily involves the whole of the spermatic cord, and especially the vas deferens, and spermatic veins, which often become varicose. Sometimes it is transferred from one testis to the other. However high the inflammation, it is seldom known to suppurate, and never if proper treatment be early adopted.

The disease most frequently arises from previous gonorrhœa, and especially when the discharge has been injudiciously suppressed by astringent or saturnine injections into the urethra. When the tumefaction commences, the pain and burning in urinating ceases, and the discharge retires altogether; but all these symptoms return so soon as the inflammation in the testicle is removed. Strangury, to an alarming extent, sometimes accompanies the swelling and stopping of the discharge, and hence, many judicious practitioners invite the return of the secretion from the urethra, thus removing the hernia humoralis more speedily.

Hernia humoralis, although most frequently connected with gonorrhœa, may arise, as already intimated, from strictures, bougies, or any other irritation in the urethra, so that the disease cannot be considered as possessing a specific character, but is purely sympathetic; hence, buboes of the same character, and produced in the same way, are not unfrequently found at the same time in the inguinal glands. It has been contended by some that this disease is not seated in the testis, but in the epididymis, and they therefore object to its being called orchitis. But in the early stage of the disease, a soft, pulpy enlargement of the gland itself will be invariably found, though the epididymis at the base of the testis will be found soon to become swollen, and then becomes the hardest part of the tumour.

This disease is often mistaken for other affections of the same organ, and it is therefore important to define the diagnosis. It may be distinguished from hydrocele by the pain it inflicts, especially when recent, and when chronic, as it sometimes is, by its want of transparency, and the peculiar hardness of the epididymis. It may be distinguished from sarcocele by its small increase of weight compared with the enormous size it sometimes acquires. It may be known from scirrhous cancer or scrofula, by these diseases being slow in their progress, while this comes on very suddenly and very soon arrives at its height. These diagnostics should not be lost sight of, as mistakes very often occur of a most mischievous kind, and of these I have known many. The difference between this disease and any species of hernia is sufficiently obvious, and offer an adequate objection to its name.

The treatment of this disease, although the peculiar province of the physician, is often submitted to the surgeon. It consists of depletion, either by venesection, leeches, or, what some prefer, scarifications to the scrotum. Emetics and the refrigerant cathartics may be necessary, and are often judiciously superadded. A warm fomentation of chamomile flowers, poppy, or hops will be found preferable to the cold applications so often recommended, and especially as there is no fear of suppuration.—*Reese*]

I have stated, that sarcoceles, in common with the generality of other sarcomatous tumours, may change into distempers which, in point of malignity and the manner in which they injure the health, are quite as bad as cancer itself. It is said, however, that sarcocele of the epididymis rarely becomes malignant, and is much more easy of cure than the same disease of the glandular portion of the testicle; but both parts are often diseased together.

Sarcoceles sometimes continue for years, without undergoing any particular change; in other instances, they increase with surprising rapidity. The inconveniences which they excite, often proceed chiefly from their weight and magnitude: their weight occasions an uneasy, and even a painful sensation in the loins, especially when the patient neglects to wear a suspensory bandage, or a bag-truss, for the support of the part. The danger of a sarcocele arises from the increase and extension of the hardness up the spermatic cord, and from the change of the tumour from its indolent state into a painful, ulcerated, and incurable disease.

A sarcocele sometimes bears a resemblance to hydrocele of the tunica vaginalis. It may have the usual pyramidal shape of the latter disease, and, like it, is always situated at the lower end of the spermatic cord. The chief difference between the two cases seems to be, that the sarcocele is hard, while the hydrocele has a soft, yielding, elastic feel. It should be known, however, that the fungus hæmatodes of the testicle is remarkable for the deceitful feel of fluctuation and elasticity which it presents; and every surgeon ought to be aware, that a sarcocele is not always particularly hard, and that hydroceles are sometimes exceedingly indurated. The sarcocele, indeed, is not transparent; neither is the hydrocele in certain instances; and these are cases in which a mistake may easily be made. Still, with due attention, both diseases may be discriminated with tolerable precision. The sarcocele, when held in the surgeon's hand, seems heavier than the hydrocele. Every part of a diseased testicle is seldom equally indurated, so that the sarcocele is usually much softer in some places than others. The hydrocele presents the same kind of feel at every point, except behind, where the testicle is felt. When, in the case of hydrocele pressure is made in this latter situation, the patient experiences a much more acute sensation than when the pressure is made upon any other part of the tumour; but, in the example of sarcocele, the patient commonly has the same kind of feel, let the pressure be applied to any part of the swelling whatsoever. When the upper portion of the spermatic cord can be felt, and it seems quite hard and thickened, the surgeon has reason for suspecting the case to be a sarcocele. Lastly, though a hydrocele, when gently handled, may seem very hard, yet, on being more strongly compressed, it will generally betray a soft elastic feel, which, excepting in instances of fungus hæmatodes, is never the case with an indurated sarcocele.

It has been already explained, that a sarcocele is sometimes conjoined with a hydrocele, which case is well known among surgeons by the appellation of *hydrosarcocele*. As the diseased testicle is then surrounded with fluid, it cannot be felt and examined by the fingers. However, when an unusual degree of hardness is perceptible at the back part of the tumour, where the testicle is situated, or when the upper portion of the spermatic cord is found to be quite indurated, there is reason for suspecting that the testicle is diseased. The sarcocele, also, is commonly the original and principal complaint, the hydrocele not occur-

ring till some time after the enlargement of the testicle.

In some unusual cases, the substance of the scrotum is converted into an indurated mass, which occasionally attains a vast size, and presents the appearance of an enormous sarcocele. An example in which the tumour weighed 70lbs. has been published by Dr. Titley.—(See *Med. Chir. Trans. vol.* 6, *p.* 73.)—In one case, recorded by Dr. Cheston, a swelling of this kind was as large as a child's head. On dissection of the parts, the testicle and tunica vaginalis were found to be quite free from disease. The tumour proceeded entirely from an induration of the cellular membrane, which immediately covers the external surface of the vaginal coat. This curious disease is more common in warm climates, and several instances of it were met with in Egypt by Baron Larrey.—(See *Mém. de Chir. Militaire*, *t.* 2, *p.* 110, *et seq.*) Mr. E. Tothill, lately of Staines, showed me a case in which he had removed from the scrotum a large mass of fat, containing the testes, and also a hydrocele.

The operation of castration is the most certain means of relieving the patient from sarcocele. This measure, however, is not invariably practicable, nor is it always necessary; for sometimes the induration of the testicle admits of being dispersed by the judicious employment of internal medicines and external applications. The hope of accomplishing this desirable object may be reasonably entertained, when the swelling is not very large, when it has not existed a considerable time, and when it is not attended with very great induration. Experience has proved, that some kinds of sarcocele have yielded to the exhibition of emetics (*Warner, Pringle, and Home, in Chemical Experiments*); to a decoction of ononis spinos (*Bergius Mat. Med. Richter's Chir. Bibl. b.* 7, *p.* 605); to cicuta and bark (*Warner*); to mercurial frictions (*Le Dran, B. Bell, Richerand, Deipech*); to the external use of the liquor ammon. acetatis, and camphorated mercurial ointment; to poultices containing opium (*Fothergill, in Med. Obs. and Inq. vol.* 5); to a lotion made of a strong decoction of hemlock (*Warner*); to the steam of vinegar, the repeated employment of leeches, and the application of cold, &c. It also behooves me particularly to mention, that the internal and external use of the preparations of iodine are found to be attended with strongly marked efficacy in various chronic affections of the testicle, especially those reputed to be scrofulous. Many facts of this kind have been reported to me by my professional friends, similar ones I have witnessed myself, and they are well worthy of being remembered in practice.—(See *Iodine.*) The operation of all these means may be advantageously promoted by the continual use of a bag-truss, the observance, as much as possible, of a horizontal position, and attention to a suitable low diet.

Mr. Pott believed, that the man who has the misfortune to be afflicted with a sarcocele, has very little chance of getting rid of the disease by any plan, except extirpation; and all the time the operation is deferred he carries about him a part, not only useless, but burdensome, and which is every day liable to become worse and unfit for such an operation. Now, although there is a great deal of truth in this opinion, yet, I conceive, it is rather exaggerated, and that it would tend to authorize the practice of castration to an extent beyond all necessity. I certainly think with Mr. Pott, that there never was a sarcocele cured, where the organization of the testicle had been destroyed by disease, or where its structure had suffered so much as to render it incapable of the office for which it is destined. But such state cannot always be known by inspection, or manual examination; and were a surgeon to condemn to the knife every testicle which he finds affected with indolent swelling and induration, and not readily curable, he would remove many which, under some of the above plans of treatment, might be perfectly cured. That there are some chronic enlargements of the testicle, which may be resolved, is a truth, of which experience must have convinced the generality of surgeons.

The scrofulous induration, and several other swellings of this organ, which are very imperfectly understood, may sometimes be benefited, and even entirely cured, just like some analogous affections of the breast. What is termed the *venereal sarcocele* (Mr. Pott allows) always gives way to a mercurial course, properly conducted. The diagnosis of this case, it must be confessed, is not very clearly explained by surgical writers, nor was its reality acknowledged by Mr. Hunter. According to Mr. Pott, it is seldom an early symptom; and he does not remember ever to have seen an instance in which it was not either immediately preceded or accompanied by some other appearances plainly venereal. He adds, that it has neither the inequality nor darting pains of scirrhus. But the question whether the case is truly syphilitic or not, is far less interesting than the question whether there are not many sarcoceles which may be diminished and cured by mercury? The affirmative cannot be questioned. I have seen many such cases myself, and there are numerous examples on record. A statement of several has been lately published by Richerand.—(See *Nosographie Chirurgicale*, *t.* 4, *p.* 300, *et seq. edit.* 4.) The authority of Delpech is also on the same side.—(*Précis Elémentaire des Maladies Reputées Chir. t.* 3, *p.* 564.)

Indeed, this last writer maintains, that many common sarcoceles and scirrhi of the testicle are so much alike in their symptoms, that the difference of their nature cannot always be at once detected by the practitioner. Hence, although I am an advocate for the early performance of castration in cases of sarcocele, when there is reason to suppose the disease so far advanced that the organization of the testicle is totally destroyed; or where internal and external remedies have been tried a certain time in vain; yet these sentiments do not incline me to recommend the operation for other examples, in which the diseasc is quite recent, and no plan of treatment whatsoever has been fairly tried. I have already enumerated various plans of treatment, which have been proved by experience to be sometimes capable of affording relief. The disease of the testicle, which is usually called the *scrofulous sarcocele*, like other forms of scrofula, often gets well spontaneously after a certain time, and it may frequently be considerably benefited by administering internally the conium maculatum, and small doses of the submuriate of mercury; lotions of sea-water, or poultices of seaweeds, being applied to the scrotum. The good effects of iodine in such cases, I have already noticed. Several other indolent enlargements of the testicle yield to frictions with camphorated mercurial ointment on the scrotum. The late Mr. Ramsden thought that some sarcoceles might be relieved by removing with bougies a supposed morbid irritability of the urethra, with which his theories led him to connect the origin of the complaint.—(See *Pract. Obs. on Sclerocele, &c.*) The novelty of this suggestion, for a time, attracted considerable notice; but the interest which it once excited has now died away; a sufficient proof, to my mind, that the practice inculcated was not of much value.

From the preceding observations, it may be inferred that all chronic enlargements of the testicle are not incurable; but that we ought at the same time to be duly impressed with the expediency of not wasting too much time in the trial of means which are not to be depended upon, and which, if continued immoderately long, might allow the disease to advance too far to be capable of being afterward effectually extirpated. According to Mr. Pott, the circumstances in which the operation of castration is advisable or not are of two kinds, and relate either to the general habit of the patient, and the disorders and indispositions of some of the viscera, or to the state of the testicle and spermatic cord.

A pale, sallow complexion, in those who used to look otherwise; a wan countenance, and loss of appetite and flesh, without any acute disorder; a fever of the heetic kind; and frequent pain in the back and bowels; are, in those who are afflicted with a scirrhous testicle, such circumstances as would induce a suspicion of some latent mischief in some of the viscera; in which case, as Mr. Pott truly observes, success from the mere removal of the testicle is not to be expected. They whose constitutions are spoiled by intemperance previous to their being attacked with this disease, who have hard livers and anasarcous limbs, he says, are not proper subjects for such an operation. Hard tumours within the abdomen, in the regions of the liver, spleen, kidneys, or mesentery, implying a diseased state of the said viscera, are very material objections to the removal of the local evil in the scrotum. In short, whenever there are manifest

appearances or symptoms of a truly diseased state of any of the principal viscera, the success of the operation becomes very doubtful.

"The state of the mere testis can hardly ever be any objection to the operation; the sole consideration is the spermatic cord: if this be in a natural state and free from disease, the operation not only may, but ought, to be performed, let the condition of the testicle be what it may; if the spermatic cord be really diseased, the operation ought not to be attempted." And Mr. Pott afterward remarks, "When the spermatic vessels are not only turgid and full, but firm and hard; when the membrane which invests and connects them has lost its natural softness and cellular texture, and has contracted such a state and such adhesions as not only greatly to exceed its natural size, but to become unequal, knotty, and painful, upon being handled; and this state has possessed all that part of the cord which is between the opening in the oblique muscle and testicle; no prudent, judicious, or humane man will attempt the operation; because he will, most certainly, not only do no good to his patient, but will bring on such symptoms as will most rapidly as well as painfully destroy him.

"On the other hand," says Pott, "every enlargement of the spermatic cord is not of this kind, nor by any means sufficient to prohibit or prevent the operation.

"These alterations or enlargements arise from two causes, viz. a varicose dilatation of the spermatic vein, and a collection or collections of fluid in the membrane investing and enveloping the said vessels." Shortly afterward the same practical writer continues: "The diseased state of a truly scirrhous testicle, its weight, and the alteration that must be made in the due and proper circulation of the blood, through both it and the vessels from which it is dependent, may and do concur in inducing a varicose dilatation of the spermatic vein, without producing that knotty, morbid alteration and hardness which forbid our attempts. Between these, a judicious and experienced examiner will generally be able to distinguish.

"In the former (the truly diseased state), the cord is not only enlarged, but feels unequally hard and knotty; the parts of which it is composed are undistinguishably blended together; it is either immediately painful to the touch, or becomes so soon after being examined; the patient complains of frequent pains shooting up through his groin into his back; and from the diseased state of the membrane composing the tunica communis, such adhesions and connexions are sometimes contracted, as either fix the process in the groin or render it difficult to get the finger and thumb quite round it.

"In the other (the mere varicose distention), the vessels, though considerably enlarged and dilated, are nevertheless smooth, soft, and compressible; the whole process is loose and free, and will easily permit the fingers of an examiner to go quite round it, and to distinguish the parts of which it is composed; it is not painful to the touch; nor does the examination of it produce or occasion those darting pains which almost always attend handling a process malignantly indurated."

Mr. Pott next explains, that "in the cellular membrane leading to a diseased testicle, it is no very uncommon thing to find collections of extravasated fluid. These, as they add considerably to the bulk and apparent size of the process, make the complaint appear more terrible; and, as I have just said, less likely to admit relief.

"When the extravasation is general through all the cells of the investing membrane, and the spermatic vessels themselves are hardened, knotty, and diseased, the case is without remedy; for, although a puncture or an incision will undoubtedly give discharge to some or even the greatest part of the fluid, yet this extravasation is so small and so insignificant a circumstance of the disease, and the parts in this state are so little capable of bearing irritation, that an attempt of this kind must be ineffectual, and may prove mischievous.

"But, on the other hand, collections of water are sometimes made in the same membrane from an obstruction to the proper circulation through the numerous lymphatics in the spermatic process, while the vessels themselves are really not diseased, and therefore very capable of permitting the operation. In this case, the fluid is generally in one cyst or bag, like to an encysted hydrocele, and the spermatic cord, cyst and all, are easily moveable from side to side; contrary to the preceding state, in which the general load in the membrane fixes the whole process, and renders it almost immoveable.

"A discharge of the fluid will, in this case, enable the operator to examine the true state of the process, and, as I have twice or thrice seen, put it into his power to free his patient from one of the most terrible calamities which can befall a man."—(See *Pott on Hydrocele, &c.*)

The testicle is subject to a disease often called *soft cancer*, which, though of a very malignant and incurable nature, is different from the true cancer already described. It has been particularly noticed by Mr. Abernethy, under the name of *Medullary Sarcoma*. In most of the instances which this gentleman has seen, the tumour, when examined after removal, appeared to be of a whitish colour, resembling on a general and distant inspection the appearance of the brain, and having a pulpy consistence. He has also often seen it of a brownish-red appearance.

This disease is now generally considered to be fungus hæmatodes. If there are any differences, they consist in the parts sloughing out and then healing, instead of a fungus shooting out, and continually increasing in size.—(See *Fungus Hæmatodes.*)

Dr. Baillie has noticed some affections in which the testicle becomes bony, cartilaginous, &c.; but on these it is not necessary for me to dwell in this Dictionary. The preceding observations may be considered as relating expressly to the diseases for which castration is generally performed.—(See *Castration.*)

Besides the fungus which arises from the testicle in the advanced stage of carcinoma, and the bleeding fungous growth which arises from this organ in the ulcerated state of fungus hæmatodes, there is another superficial fungous excrescence, to which the testicle is subject, and which is entirely free from all malignancy. The disease to which I refer has been noticed by Callisen, under the name of *lipoma of the testicle*. "Si ex superficie albugineæ vel ipsa tunica vaginali excrescentiæ surgunt, totum demum testem involventes, et scirrhum seu fungum, mentientes ipsius tamen testis substantia parum aut vix de statu naturali aberrante; malum naturam lipomatis sequitur, vix unquam in scirrhum et carcinoma abiens."—(See *Systema Chirurgiæ Hodiernæ, vol. 2, p. 145, edit.* 1800.) The *superficial fungus*, or *lipoma of the testicle*, was noticed in an early edition of another publication: and described as "a particular affection of the testicle, in which a fungus grows from the glandular substance of this body, and, in some instances, from the surface of the tunica albuginea. This excrescence is usually preceded by an enlargement of the testicle, in consequence of a bruise or some species of external violence. A small abscess takes place and bursts, and from the ulcerated opening the fungus gradually protrudes." I then proceeded to represent how unnecessary and improper it was to extirpate the testicle on account of this affection, if, after the subsidence of the inflammation, the part should not seem much enlarged and indurated. I recommended the fungus to be cut off or else destroyed with caustic; and I founded my advice on a successful attempt of the first kind, which was made in St. Bartholomew's Hospital, by Sir James Earle, a little while before my book was published.—(See *First Lines of the Practice of Surgery, p.* 399.)

An interesting little paper has also been written on the subject by my friend Mr. Lawrence, who has favoured the public with a more particular account, and nine cases illustrative of the causes, symptoms, and progress of the disorder. According to Mr. Lawrence, the patient generally assigns some blow or other injury as the cause of the complaint; in other instances, it originates in consequence of the hernia humoralis from gonorrhœa, and sometimes appears spontaneously. A painful swelling of the gland, particularly characterized by its hardness, is the first appearance of the disease. After a certain length of time the scrotum, growing gradually thinner, ulcerates; but the opening which is thus formed, instead of discharging matter, gives issue to a firm and generally insensible fungus. The surrounding integuments and cellular substance are thickened and indurated by the complaint, so that

there appears to be altogether a considerable mass of disease. The pain abates and the swelling subsides considerably, when the scrotum has given way. In this state the disorder appears very indolent; but if the fungus be destroyed by any means, the integuments come together, and a cicatrix ensues, which is inseparably connected with the testicle. Mr. Lawrence next informs us, that if the part be examined while the fungus still remains, the excrescence is found to have its origin in the glandular substance of the testicle itself; that the coats of the part are destroyed to a certain extent; and that a protrusion of the tubuli seminiferi takes place through the aperture thus formed. Mr. Lawrence says he has often ascertained the continuity of the excrescences with the pulpy substance of the testicle, of which more or less remains according to the difference in the period of the disorder. The same gentleman thinks that the glandular part of the testicle experiences an inflammatory affection in the first instance, in consequence of the violence inflicted on it; and that the confinement of the swollen substance, by the dense and unyielding tunica albuginea, sufficiently explains the peculiar hardness of the tumour, and the pain which is always attendant on this stage of the disorder. The absorption of the coats of the testis and of the scrotum obviates the tension of the parts, and thereby restores ease to the patient at the same time that the fungus makes its appearance externally.

With regard to the treatment, Mr. Lawrence is of opinion, that, if the complaint were entirely left to itself, the swelling would probably subside, the fungus shrink, and a complete cure ensue without any professional assistance; but, he adds, that the disorder is so indolent in this stage, that a spontaneous cure would not be accomplished till after much time. He says, that the excrescence may be removed with a knife, or, if the nature of its attachment permit, with a ligature, or that it may be destroyed with escharotic applications. Mr. Lawrence very judiciously gives the preference to removing the tumour to a level with the scrotum by means of the knife, as the most expeditious and effectual mode of treatment. He can discern no ground whatever for proposing castration in this malady, since in no part of its progress, nor in any of its possible consequences and effects, can it expose the patient to the slightest risk.

Mr. Lawrence also mentions the possibility of there being other kinds of fungi, which may be met with growing from the testicle, and quotes an instance in which Dr. Macartney found a fungus, of a firm and dense structure, growing from the tunica albuginea, while all the substance of the testicle itself was sound. Dr. Macartney was so kind as to show me the preparation, affording a clear specimen of the second kind of fungus. The cases drawn up by Mr. Lawrence are, in my opinion, highly interesting, and may be read in the *Edinb. Med. and Surg. Journal for July*, 1808.

I have already noticed, that Callisen represents the lipoma as sometimes originating from the surface of the tunica vaginalis; a kind of case which has not yet fallen under my observation.

In the preface to the third edition of this Dictionary, p. 10, I quoted a case, published by Dr. H. Weinhold, in which the operation for bubonocele was performed; and as the testicle was diseased, the surgeon made a complete division of the spermatic cord, tied the spermatic arteries, and then left the testicle in its natural situation. After a time, the absorbents had diminished the part to a very inconsiderable little tumour.—(See *Journ. der Pract. Heilkunde von C. W. Hufeland und K. Himly*, 1812. *Zehntes. Stück*, p. 112.) This case merits attention, and ought to have been cited in the article *Castration*, because it is the first instance, I believe, in which such practice was tried. Subsequently the following work has been published: "*Nouvelle Méthode de traiter le Sarcocele, sans avoir recours à l'Extirpation du Testicule, par C. Th. Maunoir*, 8vo. *Genève*, 1820." The new plan consists in dividing and tying the spermatic arteries, and leaving the rest of the cord and the testis undisturbed.

TETANUS. (From τείνω, to stretch.) Tetanus is defined by all authors to be a more or less violent and extensive contraction of the muscles of voluntary motion, attended with tension and rigidity of the parts affected.

The excessive contraction of the muscles is kept up without any intervals of complete relaxation; in which respect the disorder differs from ordinary spasms and convulsions, where the contractions and relaxations alternate in rapid succession. In tetanus, the powers of sensation and intellect also remain unimpaired, in which particularity it forms a contrast to epilepsy.—(*Rees's Cyclopædia, art. Tetanus.*)

When its effects are confined to the muscles of the jaw or throat, it is called *trismus* or *locked-jaw*; when all the body is affected and becomes rigid, but retains its ordinary straightness, the case is named *tetanus*. When the body is bent forwards, the disease is termed *emprosthotonos*; and *opisthotonos*, when the muscles of the back are principally affected.

To these four forms some writers have added a fifth, which they denominate *pleurosthotonos*, and which is characterized by the body being drawn to one side. It is the *tetanus lateralis* of Sauvages.

The different terms which are applied to tetanic affections do not imply so many particular diseases; but only the seat and various degrees of one and the same complaint.

A far more important division of tetanus is into the *acute* and *chronic*, according to its greater or less intensity. The first is exceedingly dangerous, and usually fatal; while the latter, on account of the more gradual progress of the symptoms, affords more opportunity of being successfully treated.—(*Larrey, in Mém. de Chirurgie Militaire, t.* 1, *p.* 235, 236.)

Tetanus may also be distinguished into the *traumatic*, or that arising from wounds, being the case with which surgeons have principally to deal; and into the *idiopathic*, or that proceeding from a variety of other causes.

Traumatic tetanus sometimes comes on in a surprisingly sudden manner, and quickly attains its most violent degree. The most rapidly fatal case that has ever been recorded is one that we have on the authority of the late Professor Robison, of Edinburgh. It occurred in a negro, who scratched his thumb with a broken china plate, and died of tetanus a quarter of an hour after this slight injury.—(See *Rees's Cyclopædia, art. Tetanus.*) But commonly the approaches of the disorder are more gradual, and it slowly advances to its worst stage. In this sort of case the commencement of the disorder is announced by a sensation of stiffness about the neck; a symptom which, increasing by degrees, renders the motion of the head difficult and painful. In proportion as the rigidity of the neck becomes greater, the patient experiences about the root of the tongue an uneasiness which soon changes into a difficulty of mastication and swallowing, which after a time become totally impossible. The attempt at deglutition is attended with convulsive efforts, especially when an endeavour is made to swallow liquids; and so great is the distress which accompanies these convulsions, that the patient becomes very reluctant to renew the trials, and refuses all nourishment. Sometimes it even inspires him with a dread of the sight of water, and a great resemblance to hydrophobia is produced.

One of the next remarkable symptoms is a very severe pain at the bottom of the sternum, darting from this point backwards to the spine, in the direction of the diaphragm. As soon as this pain commences, the spasms of all the muscles about the neck become exceedingly violent, and the head is drawn backwards or forwards, according as the contraction of the extensor or flexor muscles happens to be strongest; but, in the majority of cases, the head and trunk are curved backwards (*Boyer, Traité des Mal. Chir. t.* 1, *p.* 288), and the contractions increasing in force, the body is frequently raised in the form of a bow, resting upon the head and feet alone; a state which is more particularly denominated *opisthotonos*.—(See *Rees's Cyclopædia, art. Tetanus.*) At the same time the muscles which close the lower jaw, and which were affected with spasm and rigidity in the very beginning of the disorder, now contract with great power, so as to maintain the lower jaw-bone inseparably applied to the upper one. The last state, which has been considered as a particular affection under the name of *trismus*, or the *locked-jaw*, Boyer conceives, may be regarded as the pathognomonic symptom of tetanus, which in many instances is limited to such an affection of the jaw.

The muscles affected in tetanic cases are never altogether relaxed as long as the disease continues; but

still they become more violently contracted in the frequent paroxysms of spasm, which always attend the complaint, and increase as it advances.

The continuance of the disease is marked by the increasing spasm of the diaphragm, which now returns every ten or fifteen minutes, and is instantly succeeded by a stronger retraction of the head and rigidity of the muscles of the back, and even of those of the lower extremities. The abdominal muscles are also strongly contracted, so that the belly feels as hard and tense as a board. By the violence of the contractions, indeed, the recti muscles have been known to be lacerated, as I shall relate an example of hereafter. Sometimes the spasm and tension extend only to the muscles on one particular side of the body: the *tetanus lateralis* of Sauvages, and the *pleurosthotonos* of other nosologists.

When the disease reaches its most violent stage, the flexor muscles of the head and trunk contract so powerfully, that they counterbalance the force of the extensors, and hold those parts in a straight, fixed, immoveable position. This is the condition to which the appellation of *tetanus* more particularly belongs. The muscles of the lower extremities become rigid; and even the arms, which till now were little affected, also partake of the general spasm and stiffness, with the exception of the fingers, which often retain their moveableness to the last. The tongue likewise continues a long while endued with the power of voluntary motion; but at length the violent spasms do not leave it unaffected, and it is then liable to be forcibly propelled between the teeth, where it is sometimes dreadfully lacerated.

In the extreme period of the disorder all the muscles destined for voluntary motion are affected; among others those of the face: the forehead is drawn up into furrows; the eyes, sometimes distorted, are generally fixed and motionless in their sockets; the nose is drawn up; and the cheeks are retracted towards the ears; so that the features undergo a most extraordinary change. When tetanus arrives at this stage, and the spasms are universal, a violent convulsion usually puts an end to the patient's misery.

Wherever the muscular contractions are situated in cases of tetanus, they are always accompanied with the most excruciating pain. They sometimes last, without any manifest remission, to the end of the disorder; but in almost all cases their violence, and the sufferings excited by them, undergo periodical diminutions every minute or two. The relaxation, however, is never such as to let the muscles which experience it yield to the action of their antagonists; and it is in nearly all cases followed in ten or twelve minutes by a renewal of the previous contractions and suffering. The recurrence of these aggravated spasms frequently happens without any evident cause; but it is often determined by efforts which the patient makes to change his posture, swallow, speak, &c.

As Dr. Cullen observes, the attacks of this disease are seldom attended with any fever. When the spasms are general and violent, the pulse is contracted, hurried, and irregular, and the respiration is affected in like manner; but during the remission both the pulse and the respiration usually return to their natural state. The heat of the body is commonly not increased; frequently the face is pale, with a cold sweat upon it; and very often the extremities are cold, with a cold sweat over the whole body. When, however, the spasms are frequent and violent, the pulse is sometimes more full and frequent than natural; the face is flushed, and a warm sweat is forced out over the whole body.

"Although fever be not a constant attendant of this disease, especially when arising from a lesion of nerves; yet, in those cases proceeding from cold, a fever sometimes has supervened, and is said to have been attended with inflammatory symptoms. Blood has often been drawn in this disease; but it never exhibits any inflammatory crust; and all accounts seem to agree, that the blood drawn seems to be of a looser texture than ordinary, and that it does not coagulate in the usual manner.

"In this disease the head is seldom affected with delirium or even confusion of thought, till the last stage of it; when, by the repeated shocks of a violent distemper, every function of the system is greatly disordered.

"It is no less extraordinary, that in this violent disease, the natural functions are not either immediately or considerably affected. Vomitings sometimes appear early in the disease, but commonly they are not continued; and it is usual enough for the appetite of hunger to remain through the whole course of the disease; and what food happens to be taken down seems to be regularly enough digested. The excretions are sometimes affected, but not always. The urine is sometimes suppressed, or is voided with difficulty and pain. The belly is costive; but, as we have hardly any accounts, excepting of those cases in which opiates have been largely employed, it is uncertain whether the costiveness has been the effect of the opiates or of the disease. In several instances of this disease, a miliary eruption has appeared upon the skin; but whether this be a symptom of the disease, or the effect of a certain treatment of it, is undetermined. In the mean while, it has not been observed to denote either safety or danger, or to have any effect in changing the course of the distemper."—(*First Lines of Physic*, *vol.* 3.)

According to Baron Larrey, the opisthotonos is not so often observed in Egypt as the emprosthotonos; and the experience of this gentleman taught him that the former was the most rapidly fatal. We must not adopt, however, his curious opinion, that the violent extension of the vertebræ of the neck and the manner in which the head is thrown back, cause strong compression of the spinal marrow, and a permanent contraction of the larynx and pharynx (*Mém. de Chirurgie Militaire*, *t.* 1, *p.* 240), since this sort of compression, if it did not at once destroy the patient, would at any rate paralyze most of the muscles, and instantly stop their extraordinary contraction.

This experienced writer notices how much the nerves of the neck and throat seem generally to be affected on the invasion of this disease. The consequent contraction of the muscles of these parts he says, is soon attended with difficulty of deglutition and respiration. The patients then experience, if not a dread of liquids, at least a great aversion to them, which often prevents the administration of internal remedies; and if the wound is out of reach of the interference of art, the patient is doomed to undergo the train of sufferings attendant on this cruel and terrible disorder. Nothing can surmount the obstacles which present themselves in the œsophagus. The introduction of an elastic gum catheter into this canal, through the nostrils, is followed by convulsions and suffocation. "I have tried this means (says Larrey) on the person of M. Navailh, a surgeon of the second class, who died of a locked-jaw, brought on by a wound of the face, accompanied with a comminuted fracture of the bones of the nose, and part of the left orbit.

"In the examination of the bodies of persons dead of tetanus, I have found the pharynx and œsophagus much contracted, and their internal membrane red, inflamed, and covered with a viscid reddish mucus.

"Hydrophobia, hysteria, and several other nervous diseases, likewise produce their chief effects upon these organs, and the result appears to be the same. So I have just remarked, when tetanus is arrived at its worst degree, the patients have a great aversion to liquids, and if they are forced to swallow them, immediate convulsions are excited. This circumstance was particularly observed in M. Navailh."—(*Mém. de Chirurgie Militaire*, *t.* 1, *p.* 247, 248.)

Sometimes tetanic affections deviate from their ordinary course and nature. The most singular of these anomalies is recorded by Sir Gilbert Blane: it is a case in which tetanus prevailed to a very considerable extent, without any degree of pain. The spasms were accompanied with a tingling sensation, which was even rather agreeable than distressing. The case, however, terminated fatally; but to the last, no pain was experienced. In two examples mentioned by the same author, the spasms affected only the side of the body in which the wound was situated.

The dissection of patients who have died of tetanus has thrown no light upon the nature of this fatal disorder. Sometimes slight effusions are found within the cranium; but in general, no morbid appearance whatever can be detected in the head. There is always more or less of an inflammatory appearance in the œsophagus and in the villous coat of the stomach about the cardia. But those who are conversant with dissections, must be well aware that these appearances are common to a great number of diseases, and are

uniformly met with in every case of rapid or violent death. Besides the redness and increased vascularity of these parts, Baron Larrey, as I have already stated, found the pharynx and œsophagus much contracted and covered with a viscid reddish mucus. He also found numerous lumbrici in the bowels of the several patients who died.—(See *Mém. de Chir. Militaire, t.* 3, *p.* 267.) This, however, could only be an accidental complication, and not a cause. In several cases, Dr. M'Arthur found the intestines much inflamed; and in two of them a yellow waxy fluid, of a peculiar offensive smell, covered their internal surface; but whether the inflammation was primary or only a consequence of the pressure of the abdominal muscles, which contract so violently in this disease, he is unable to decide.—(See *Med. Chir. Trans. vol.* 7, *p.* 475; *and Rees's Cyclopædia, art. Tetanus.*)

Dr. Lionel Chalmers, of Charleston, South Carolina, states, that when the disease forms very quickly, and invades the unfortunate persons with the whole train of its mischievous symptoms in a few hours, the danger is proportioned to the rapidity of the attack, and that the patients thus seized generally die in twenty-four, thirty-six, or forty-eight hours, and very rarely survive the third day. But when the disease is less acute, few are lost after the ninth or eleventh.—(See *Med. Obs. and Inq. vol.* 1, *p.* 92, 93.)

From the valuable report of Sir James Macgregor, it appears that several hundred cases of tetanus occurred in our army during the late campaigns in Spain and Portugal. The disease was observed to come on at uncertain periods after the receipt of the local injury; but it terminated on the second, third, and fourth days, and even as late as the seventeenth and twentieth day; though it was usually not protracted beyond the eighth.—(*Med. Chir. Trans. vol.* 6, *p.* 353.) I had a patient, however, who lingered in the military hospital at Oudenbosch five weeks with chronic tetanus, before he died. This happened in the year 1814, soon after the assault on Bergen-op-Zoom, where the patient had been wounded, and suffered amputation of the thigh.

Although tetanus is a disease which has been observed in almost all parts of the world, experience proves that its frequency is much the greatest in warm climates, and especially in the hot seasons of those climates. It is also more common in marshy situations and countries bordering upon the sea, than in places which are very dry, elevated, and at a distance from the seacoast. Every class of individuals is exposed to its attacks; but infants, a few days after their birth, and middle-aged persons are said to be oftener affected than older subjects or others in the youthful period of life. The male sex more frequently suffer than the female; and the robust and vigorous more frequently than the weak.

According to Dr. Cullen and other medical writers, the causes of tetanus are cold and moisture, applied to the body while it is very warm, and especially the sudden vicissitudes of heat and cold. Or the disease is produced by punctures, lacerations, or other injuries. Cullen admits, however, that there are probably some other causes, which are not distinctly known.

Baron Larrey observed, that gun-shot wounds in the course of the nerves and injuries of the joints often produced tetanus in the climate of Egypt, particularly when the weather or temperature passed from one extreme to the other, in damp situations, and in those which were adjacent to the Nile or the sea. What he terms dry and irritable temperaments were the most subject to the disorder, the event of which was found to be almost always fatal.—(*Larrey, op. et loc. cit.*)

Traumatic tetanus is remarked to proceed oftener from wounds of the extremities than from similar injuries of the trunk, head, and neck. Sometimes it originates at the moment of the accident, as in the instance mentioned by the late Professor Robison of Edinburgh; but in general it does not come on till several days afterward, sometimes not till the wound is nearly or perfectly healed, and free from all pain and uneasiness. Wounds of every description may give rise to tetanus, and in warm climates very trivial injuries produce it. Thus, in Egypt, Larrey had one case, which proceeded from the lodgement of a small piece of fish-bone in one of the sinuses of the fauces.—(*Mém. de Chir. Militaire, t.* 1, *p.* 254.) In colder regions, traumatic tetanus seldom happens, except from contused, punctured, or lacerated wounds; or wounds of the ginglymoid joints, with laceration of the tendons and ligaments; compound fractures or dislocations; deep pricks in the sole of the foot; and especially lacerations or ulcerations of the fingers and toes. A partial division of a nerve has been suspected as a cause; but as some nerves must be imperfectly cut through in almost every wound, and yet tetanus does not arise, the reality of this cause is doubtful. Besides, if it were true, the cure would be easily effected, by making the division of the nerve complete, which experience contradicts. Baron Larrey, however, has recorded a fact which favours the opinion, as I shall presently notice; and a case in which the branch of the median nerve going to the thumb was found partly torn through, and its extremity inflamed and thickened, has been related by Mr. Liston.—(*Ed. Med. and Surg. Journ. No.* 79, *p.* 292.) The inclusion of the nerves in ligatures applied to arteries, is another alleged cause of tetanus; but as this fault is very common, and tetanus rather rare in this country, while it may follow all sorts of wounds, whether from accidents or operations, the accuracy of this opinion may also be doubted. In support of it, however, there are some cases and observations adduced by Larrey, which will be quoted in the sequel of this article.—(See *t.* 3 of his *Mem. de Chir. Mil.*) At the same time I do not mean to hint that the nerves are not sometimes tied in tetanic cases, or that the practice is not on every account blameable. Amputation and castration are the only great surgical operations to which I have seen tetanus succeed; though it may follow the employment of the knife on less severe occasions. In St. Bartholomew's Hospital, it once followed the operation of removing the breast.

In warm countries, tetanus is an ordinary consequence of all kinds of wounds.

There cannot be a doubt that difference of climate makes considerable difference in the degree and danger of tetanus. Larrey found that in Egypt, the disease was more intense, and bore a greater resemblance to hydrophobia than in the colder climate of Germany. In both these countries he remarked that, when the wounds causing tetanus injured nerves situated on the fore part of the body, emprosthotonos was occasioned; that if the posterior nerves were hurt, opisthotonos followed; and that when the wound extended quite through a limb, so as to injure equally both descriptions of nerves, complete tetanus ensued. He noticed, also, that the disease commonly arose from wounds when the seasons and temperature passed from one extreme to another. Exposure to the cold, damp, nocturnal air he found particularly conducive to it.—(See *Mém. de Chir. Milit. t.* 3, *p.* 286.)

In the late campaigns in Spain and Portugal, according to the report of Sir James Macgregor, tetanus occurred in every description and in every stage of wounds, from the slightest to the most formidable: it followed the healthy and the sloughing; the incised and the lacerated; the most simple and the most complicated. It occurred at uncertain periods; but it was remarked that, if it did not commence before twenty-two days from the date of the wound, the patient was safe.—(See *Med. Chir. Trans. vol.* 6, *p.* 453.) In Egypt, as we learn from Larrey, the latest period of the commencement of tetanus after a wound, was from the fifth to the fifteenth day.—(*Mém. de Chir. Militaire, t.* 1, *p.* 263.)

It is observed by Dr. Dickson, that as the acute form of tetanus is so uniformly fatal, it is of the greatest consequence to attend to whatever may assist in detecting the disease early, or in warding it off. Richerand states, that in wounds threatening convulsions and tetanus, a persevering extension of the limbs during sleep often manifests itself before any affection of the lower jaw; and we should naturally pay more attention to any admonition of this kind in punctured or extensive lacerated wounds, particularly of tendinous or ligamentous parts, and especially in injuries of the feet, hands, knee-joint, back, &c. Some prelusive indications of danger may often be derived from the increase of pain, irritation, restlessness, nervous twitchings, pain and difficulty in deglutition, or in turning the head; spasms or partial rigidity of some of the voluntary muscles; pain at the scrobiculis cordis; a suppressed or vitiated state of the discharge, &c. which mark the slower approaches of the disease. Larrey adduces several instances of tetanus, in which the

wound was either dry or afforded only a scanty serous exudation, and where the symptoms were relieved on suppuration being re-established; and Dr. Reid (*Edinb. Med. and Surgical Journal for July*, 1815) remarks, that on removing the dressing, the wound was covered with a darkish unhealthy-looking matter, and that he had seen this change the forerunner of tetanus in two other instances. A torpor of the intestines has generally been observed to precede as well as accompany the disease, and Boyer, in particular, enumerates an obstinate constipation among the predisposing causes.—(*Traité des Mal. Chir. t.* 1, *p.* 287.) Mr. Abernethy also informs us, that in four cases where he inquired into the state of the bowels, the evacuations were not like feces; and he proposes as a question, in investigating the cause, what is the state of the bowels between the infliction of the injury and the appearance of this dreadful malady?—(*Abernethy's Surgical Works*, *vol.* 1, *p.* 104.) Dr. Parry thinks the velocity of the circulation a useful criterion of the danger of the disease, and observes, that if the pulse be not above 100 or 110, by the fourth or fifth day the patient almost always recovers; but that if it be quickened early, the disease mostly proves fatal, and yet there are a few instances of recovery where the pulse has risen to 120 on the first day. Baron Larrey remarks, that when the perspiration which so often attends the disease is symptomatic, it begins upon the head and extremities; but that when it is critical, it occurs over the chest and the abdomen.—(*Mémoires des Chir. Militaire*, *t.* 1, *p.* 256.) It must be confessed, however, that in many cases perspiration flows very freely, without bringing relief.—(*Rees's Cyclopædia*, *art. Tetanus.*)

I next proceed to consider the treatment of tetanus; a subject of infinite difficulty, because the disease frequently baffles every mode of practice, and, in certain instances, gets well under the employment of the very same remedies which decidedly fail in other similar cases of the disorder. Every plan has occasionally succeeded, and every plan has still more frequently miscarried. The great difficulty, therefore, is to ascertain, among numerous discordant accounts, what practice is found on the whole to be attended with the least ill-success? For in the present state of our knowledge, the most credulous practitioner will not flatter himself with the supposition, that any effectual remedy for tetanus has yet been discovered. As, however, acute tetanus was regarded by Hippocrates and the ancients as certainly mortal, and it does not always prove so in modern times, it seems allowable to conclude that the recoveries which now happen must be ascribed to improvements in practice. This reflection should lead us not to give up the subject as hopeless; but to redouble our exertions for the discovery of a more successful method of treatment, and, if possible, of some new medicine, possessing more specific power over the disorder.

As it is justly observed by a well-informed writer, when we reflect upon the obscurity which involves both the *ratio symptomatum* and the proximate cause of tetanic affections, we need not wonder that the practice in these disorders should still be entirely empirical. The indication of cure, which is generally applicable in all diseases, namely, the removal of the exciting causes, has but little place in a morbid condition, which is the consequence of causes that in general have ceased to act, or which it is not in our power either to remove or control. In those cases, where we could suppose local irritation to be still operating, the most effectual method of counteracting its effects on the system would obviously be to intercept all communication between the seat of the irritation and the sensorium. If, however, the disease has already established itself, and the severe symptoms have come on, it does not appear that this would succeed in arresting the course of the disorder. Experience has but too fully proved, that the amputation of the limb, from the injury of which the tetanus has arisen, will very seldom procure even a mitigation of the symptoms, if performed after a certain period from their first appearance.—(*Rees's Cyclopædia*, *art. Tetanus.*) Baron Larrey has been the greatest modern advocate for the performance of amputation in cases where tetanus depends upon a wound of the extremities; but the facts which he has adduced in its favour are not numerous, and *he limits his recommendation of the measures chiefly to chronic cases*, and extends it to no others, except on the very first accession of the symptoms.

"The equally unexpected and entire success (observes Larrey) obtained by the amputation of the injured limb, in the person of an officer attacked with *chronic* tetanus, leads me to propose the question, *whether, in this disorder, occasioned by a wound of some part of the extremities, it would not be better to amputate the injured limb immediately the symptoms of tetanus commence, rather than expect from the resources of nature, and from very uncertain remedies, a cure which so seldom happens?*

"If tetanus is chronic, as is sometimes observed, amputation may be done at every period of the disorder, provided a choice be made of the time when there is an intermission of the symptoms. The operation would not answer so well in acute tetanus, if the disease were advanced, and the muscles to be divided were strongly contracted and rigid, as I have observed at the siege of Acre in a soldier who was seized with tetanus, in consequence of a gun-shot wound of the left elbow."—(*Mém. de Chir. Militaire*, *t.* 1, *p.* 262.)

Larrey did, indeed, try amputation in a few instances of acute tetanus. In the case last cited, the symptoms were already considerably advanced, when the experiment of amputating the arm was made; yet, says he, the operation was followed by considerable ease. The symptoms recurred, however, a few hours afterward, and proved fatal on the third day. In another example, this gentleman repeated the experiment, though acute tetanus had begun. The operation is described as having stopped all the symptoms, as it were, by enchantment; the patient even passed twelve hours in perfect ease; but, being exposed to the damp cold air, the disorder returned, and carried him off.—(See *Mém. de Chir. Militaire*, *t.* 1, *p.* 263—269.) In a case of acute tetanus, where Mr. Liston amputated the wounded hand, the opisthotonos subsided the following day; yet the case ended fatally, and it is a question, whether the degree of temporary benefit which was obtained, did not proceed from other remedies, tried in conjunction with the operation?—(See *Ed. Med. and Surg. Journ. No.* 79, *p.* 293.)

Larrey records some cases in favour of amputation at the commencement of tetanus from wounds, and especially for the relief of the disease in the chronic form. He has likewise adduced an interesting example, in which speedy relief and a cure followed cutting off all communication between the nerves of the wounded part and the sensorium by a suitable incision.

In this place I think it right to remind the reader, that although Baron Larrey once or twice amputated when acute tetanus had somewhat advanced, he does not advise the practice; and he expressly restricts his sanction of amputation to chronic or quite incipient cases of tetanus, and to a few instances in which the ginglymoid joints are fractured, accidents which, independently of tetanus, would generally require the operation.—(See *Mém. de Chir. Mil. t.* 3.) The report of Sir James Macgregor fully confirms the statement of Larrey; namely, that free incisions are of little avail in the acute and fully-formed disease, and that amputation fails in the same kind of case. After the battle of Toulouse, this operation was extensively tried; but without success. The French are also said to have lost an immense number of soldiers from tetanus after the battle of Dresden, when, Sir James infers, that the practice of amputation must have been fairly tried.—(See *Med. Chir. Trans. vol.* 6, *p.* 456.) We have seen, however, that according to the precepts of Larrey, the French surgeons would only have performed the operation in chronic cases, which are not the most frequent, or if in other instances, only on the very first accession of the symptoms. But upon the whole, notwithstanding the partial degree of success attending Larrey's experiments, I have no hesitation in declaring my belief, that amputation of the injured part, in cases of chronic tetanus, will never be extensively adopted. The uncertain efficacy of this severe measure, and the occasional possibility of curing this form of the complaint by milder plans, will for ever constitute insuperable arguments against the practice.

Since the third edition of this Dictionary was printed, Sir Astley Cooper has published his sentiments respecting the plan of amputating in cases of tetanus

and they tend to confirm the opinion which I have always given upon the subject. In one case of tetanus, from a compound fracture just above the ankle, the operation seemed to precipitate the fatal event. In another case, the finger was amputated without any good; and a third case is referred to, in which the operation also failed in saving the patient's life. In chronic tetanus, amputation is regarded by Sir Astley Cooper as unjustifiable, as the patient often recovers without this proceeding. The medicine which has appeared to this gentleman most useful in such cases, is the submuriate of mercury joined with opium.—(*Surgical Essays, part* 2, *p.* 190.)

Mr. Abernethy, in his lectures, also disapproves of amputating any material part of the body with the view of relieving tetanus, unless the injury require the operation on other grounds: he acknowledges, however, that he has seen tetanus mitigated by the practice, though the patients ultimately fell victims to the disease.

On the subject of making incisions for the purpose of separating the nerves of the wounded part from the sensorium, Larrey states, that they should be practised before inflammation has come on; for if this has made progress, they would be useless and even dangerous. They should comprehend, as much as possible, all the nervous filaments and membranous parts; but he condemns all incisions into joints, as exasperating the symptoms of tetanus, instances of which he has witnessed. The Baron has recorded some convincing proofs of the benefit sometimes arising from completely dividing the trunk of the injured nerve. In one instance, tetanic symptoms followed an injury of the supraorbitary nerve, but were immediately stopped by dividing some of the fibres of the occipito-frontalis, and the nerves and vessels, down to the bone.

On the principle of destroying the parts which are the seat of the local irritation, Larrey also frequently applied the actual and potential cautery to the wound. The application of caustics, says he, may be practised with advantage on the first attack of the symptoms, the same precept being observed as in making the incisions. Bleeding, if necessary, and the use of topical emollients and anodynes, may follow these operations; though in general they have little effect.—(*Mém. de Chir. Militaire*, *t.* 1, *p.* 249.) In the third volume of this interesting work, *p.* 297, *&c.* are several cases in which the cautery was employed with success. We must not conclude, however, that much dependence ought to be placed in the use of the cautery, since Larrey observes, in another place, "The moxa and actual cautery, recommended by the Father of Medicine, have been equally unavailing. The moxa was employed at Jaffa upon three wounded men: the disease notwithstanding followed its usual course, and terminated fatally.

"I have cited a striking instance of the inefficacy of the second method, in a case of opisthotonos."—(*T.* 1, *p.* 258.) This author also adduces some cases which tend to support the opinion, that tetanus occasionally proceeds from the inclusion of a large nerve in the ligature applied to an artery. The son of General Darmagnac died of tetanus consequent to amputation, and upon examining the stump, the median nerve was found included in the ligature with the artery, and its extremity reddish and swollen.—(*Mém. de Chir. Mil. t.* 3, *p.* 287.) In another case, Larrey suspected the tetanic disorder to proceed from a principal branch of the crural nerve being tied together with the femoral artery, and he cut the ligature; but the relief was only partial and temporary. The cautery was therefore applied deeply to the whole surface of the stump. A marked amendment took place a few hours afterward, and the patient recovered. A diaphoretic mixture, with camphor and opium, was also exhibited.—(*T.* 3, *p.* 297.)

Among other local means for the relief of tetanus, we might as well notice the employment of blisters as near as possible to the wound, or their application, or that of the ointment of cantharides, to the wound itself. Almost all modern writers have observed, that tetanus is accompanied at its commencement and in its progress with an interruption or total cessation of suppuration in the wound. Hence, the indication to excite this process again, by the means which I have specified. Larrey seems to have adopted both plans; but he particularly applied the ointment of cantharides to the wound itself in an early stage of the symptoms, and in cases where there not only was a suppression of the discharge, but where he suspected the nerves of the wounded part had suffered from exposure to the cold damp air, on the detachment of the sloughs. For facts in favour of these local means, the reader must refer to the first and second volumes of the *Mémoires de Chirurgie Militaire.*

It appears also from Larrey's experience in Egypt, that poultices, made of the leaves of tobacco, and applied to the wounds of persons labouring under tetanus, are followed by no advantageous effect. The alkalies also proved of no service.—(*T.* 1, *p.* 257.)

I shall conclude these remarks on what may be called the local treatment of tetanus, with mentioning, that the celebrated Dr. Rush recommended the wound to be dilated and dressed with oil of turpentine (see *Trans. of the American Philos. Society, vol.* 2); and that some of our naval surgeons have used tincture of opium as a dressing.

A great degree of obscurity prevails respecting the most eligible *general* or *constitutional* plans of treating tetanus, and I am afraid, it must be confessed, that our internal remedies cannot be more depended upon than the local means already described. This opinion is fully confirmed by adverting to the discouraging fact, recorded by Sir James Macgregor, viz. that out of several hundreds of cases which occurred in the British army during the late campaigns in Spain and Portugal, there were very few which terminated successfully, or in which the remedies however varied, seemed to have any beneficial influence after the disease had made any progress.—(*Med. Chir. Trans. vol.* 6, *p.* 449.) The possibility of doing much good by internal medicines is also sometimes totally prevented by the inability of swallowing, which afflicts the patient. In short, the present state of our knowledge, respecting tetanus, will not allow us to indulge much hopes of cure from any means yet discovered, except in the chronic form of the complaint; the instances of success in the treatment of acute tetanus being by no means numerous, and not the result of any determinate plan of treatment.

Of all medicines, opium is that which has raised the greatest expectation, and been the most extensively tried in cases of tetanus. Indeed, there cannot be a doubt that, in many chronic, mild cases, it is competent to effect a cure. But for this purpose, it is absolutely necessary that its use be begun from the earliest appearance of the symptoms; that it be given in very large doses; and that the doses be repeated at short intervals, so that the system be kept constantly under the influence of the remedy. It is, indeed, astonishing how the system, when labouring under a tetanic disease, will resist the operation of this and other remedies, which, in its ordinary state, would have been more than sufficient to overpower and destroy it. Patients with tetanus will bear, with impunity, quantities of opium which at any other time would have been certainly fatal. Instances are upon record of five, ten, and even twenty grains, being taken every two or three hours, for many days, without any extraordinary narcotic effects being produced upon the sensorium. It is always advisable, however, to begin with comparatively moderate doses, such as forty or sixty drops of the tincture of opium, which may be repeated at intervals of three or four hours, and increased at each repetition until some sensible effect is produced on the spasms. It seems requisite to augment the dose rapidly, as the disease presses upon us every hour, and no time must be lost while there is yet a chance of controlling its fury. The approaching closure of the jaw, and difficulty of deglutition which may increase so as to render it hardly possible to introduce medicines into the stomach, are additional motives for pushing our remedies before such obstacles arise.—(*Rees's Cyclopædia, art. Tetanus.*) I once supposed it possible to overcome this impediment by introducing a flexible catheter down the œsophagus from one of the nostrils; but the attempt to do this always brings on a violent paroxysm of spasms, attended with such a sense of suffocation that it cannot be endured. The experience of my friend, the late Mr. Cruttwell, of Bath, and that of Baron Larrey, have fully proved, that no assistance can be derived, in these circumstances, from the use of flexible tubes.—(See *Mém. de Chir. Militaire, t.* 1, *p.* 247.) Sometimes,

however, the obstacle to the administration of medicines arising from the closure of the jaw, is prevented by loss of some of the incisor teeth, and, in a few instances, Baron Larrey adopted the plan of extracting two of them. This would be useless, however, when deglutition is totally hindered, as happened in one instance recorded by the latter eminent surgeon.—(*Op. cit. t.* 3, *p.* 301.) Clysters are the only resource when the spasm of the fauces cannot be overcome. In this way, as much as a drachm of the extract of opium has been introduced into the bowels at one dose. Opiate frictions upon the jaws, throat, and other parts of the body, have been practised. Opiate plasters have also been applied to the masseter muscles, and behind the ears. This external use of opium, however, can only be regarded as a feeble and probably useless method.

A curious fact, noticed by Mr. Abernethy in his lectures, seems to offer some explanation of the little effect of some of the most powerful medicines on the constitution in tetanus; on opening the stomach of a patient who had died of tetanus, after taking large doses of opium, thirty drachms of this substance were found undissolved in the stomach. Whether morphine will have more power over tetanus than the common preparations of opium, must be decided by farther experience; but I confess that my own expectations of so desirable a circumstance are not very sanguine.

As the costiveness always produced by tetanus is rendered still more obstinate by opium, laxative medicines and clysters should constantly accompany its employment. The testimony of the army physicians, as we learn from the report of Sir James Macgregor, is highly in favour of a rigid perseverance in the use of purgatives, given in adequate doses to produce daily a full effect. Dr. Forbes states, that a solution of sulphate of magnesia in infusion of senna was found to answer better than any other purgative; and it was daily given in a sufficient quantity to procure a copious evacuation, which was always dark-coloured and highly offensive; and to this practice he chiefly attributes, in one severe case, the removal of the disease. —(*Med. Chir. Trans. vol.* 6, *p.* 452.)

A spasmodic rigidity of the muscles being the most prominent symptom of tetanus, it was natural for practitioners to try the efficacy of some other antispasmodic medicines besides opium; and those which have been principally the subject of experiment are castoreum, ether, the conium maculatum, musk, camphor, and latterly the digitalis. In many cases, opium and camphor have been exhibited together. Indeed, Larrey asserts, that of all the medicines hitherto proposed by skilful practitioners, the extract of opium combined with camphor, and the nitrate of potassa, dissolved in a small quantity of the almond emulsion, and given in doses more or less strong, produces the most favourable effects, since patients, who have an aversion to other fluids, take with pleasure this mixture, the action of which must be promoted by bleeding, if necessary, and blisters, under the circumstances which have been specified.—(See *Mém. de Chir. Militaire, t.* 1, *p.* 271.) In the same work, several cases are detailed which were benefited by such treatment.

Although some practitioners have thought that they saw good effects result from musk, yet the majority, who have made trial of both this and camphor in cases of tetanus, have found no reason to recommend these medicines. One hundred and fifty grains of musk have been given in the space of twelve hours, to a young girl, thirteen years old, affected with an incipient tetanus; but no salutary effect on the disorder was produced.

We learn also from Sir James Macgregor, that ether, camphor, musk, and other antispasmodics, as likewise the alkalies, were tried by our military surgeons in Spain, and found unsuccessful.—(*Medico-Chir. Trans vol.* 6, *p.* 458.)

From the same authority we find, that digitalis, in large doses, was tried in several cases in the Peninsula; and that it, with several other medicines enumerated, failed in almost every case of acute tetanus which occurred.—(*P.* 454.) In one case the jaw remained fixed to the last, and the patient was never entirely free from spasms.—(*P.* 458.) I am not acquainted with the particulars of any cases in which belladonna has been given; nor whether it be a remedy worthy of farther trial.

Analogy has also led to the employment of the warm bath, as a plan which seemed to promise great benefit, by producing a relaxation of the contracted muscles. But, notwithstanding this means has appeared, in a few instances, to occasion some little relief, particularly when the practitioner has been content with mere fomentations, it generally fails, and often has even done mischief. This may perhaps be, in some measure, ascribable to the disturbance and motion which the patient must necessarily undergo in order to get into the bath; for it is very well known, that every exertion on the part of the patient is very apt to excite most violent paroxysms of spasm. The author of the article Tetanus, in the Encyclopédie Méthodique, mentions his having seen the warm bath do harm, in two or three cases in which it was expected to have done good. Though numerous writers have recommended the trial of the plan, it would be difficult to trace, in their accounts, any facts which decidedly show that its adoption has ever been followed by unequivocal benefit. The warm bath was tried in Spain, and found to produce only momentary relief.—(*Medico-Chir Trans. vol.* 6, *p.* 457.) Dr. Hillary, who practised a long while in the warm climate of America, where tetanus is very common, disapproves of this method of treatment. He observes, that although the use of the warm bath may appear to be very rational, and promise to be useful, he always found it much less serviceable than emollient and antispasmodic fomentations; and he also mentions, that he had sometimes seen patients die the very moment when they came out of the bath, notwithstanding they had not been in it more than twenty minutes, the temperature of the water being likewise not higher than 29 or 30 of Reaumur's thermometer.—(See *Hillary on the Air and Diseases of Barbadoes.*)

De Haen also relates a similar fact of a patient dying the instant he was taken out of the warm bath.

Hippocrates was an advocate for the application of cold water to tetanic patients. The advantages of the cold bath were first particularly explained by Dr. Cochrane, in the *Edinb. Medical Commentaries;* and the plan has subsequently received the praises of Dr. Wright, Dr. Currie of Liverpool, and others. Of all the remedies which have been employed in cases of tetanus, the cold bath is represented by some authors as that which has been attended with the greatest success. Dr. Wright published in the *Med. Obs. and Inq. vol.* 6, a paper containing a narrative of the first trials of this method, which were all successful. The plan is said to be preferred throughout the West Indies. It consists in plunging the patient in cold water, and in that of the sea, when at hand, in preference to any other, or else in throwing from a certain height several pails of cold water over his body. After this has been done, he is to be very carefully dried with a towel, and put to bed, where he should only be lightly covered with clothes, and take twenty or thirty drops of laudanum. The symptoms usually seem to give way, in a certain degree, but the relief which the patient experiences is not of long duration, and it is necessary to repeat the same measures at the end of three or four hours. They are to be repeated in this manner until the intervals of freedom from the attacks of the disorder increase in length. This desirable event, it is said, generally soon follows, and ends in a perfect cure. Wine and bark were sometimes conjoined with the foregoing means, and seemed to co-operate in the production of the good effects. Dr. Wright concludes the account with the following remark, sent to him with a case, by Mr. Drummond, of Jamaica:—"I am of opinion, that opiates and the cold bath will answer every intention in tetanus and such like diseases; for while the opium diminishes the irritability, and gives a truce from the violent symptoms, the cold bath produces that wonderful tonic effect so observable in this and some other cases. Perhaps the bark, joined with these, would render the cure more certain. May we not then have failed in many cases, by using opiates alone in large doses, or, what probably is worse, with the warm bath instead of the cold bath? And have we not reason to suspect, that the increased doses of opium, which seemed requisite when the warm bath was used, may have proved pernicious?"—(*Vol.* 6, *p.* 161.)

Our army surgeons who were in Spain, are said to have found the cold bath worse than useless (*Med. Chir. Trans. vol.* 6, *p.* 254); and here I beg to remark

particularly, that the plan seems to present no hope of benefit in cases of tetanus from wounds, however strong the evidence is of its utility in other examples of the disease. This was the opinion of Hippocrates, and, in modern times, that of Dr. Cullen, Callisen, &c. "Immersio subita iterata totius corporis in aquam frigidam in tetano a causa interna minorem effectum præstat."—(*Systema Chirurgiæ Hodiernæ, part* 1, *p.* 169, 170, *edit.* 1798.) On the subject of cold effusion and bathing, there are on record two cases, which are curious. One is related by Baron Larrey. It was an instance of tetanus from a gun-shot wound. The cold bath was used. The first two trials gave the patient extreme pain, and no amendment followed. The sight of the bath the next time filled him with an invincible dread of the water, into which he refused to be put. He was covered, however, with a blanket, and immersed. The tetanic stiffness was immediately increased and dreadful convulsions excited. It became necessary to remove him directly from the bath, and put him to bed. Deglutition was from this moment utterly impeded, and the contraction of the muscles carried to the most violent degree. A tumour, about as large as an egg, suddenly made its appearance near the linea alba, below the navel. After death, this was found to be caused by a rupture of one of the recti muscles, and a consequent extravasation of blood.—(See *Mém. de Chir. Mil. t.* 3, *p.* 287—289.) This case is decidedly in support of the truth of the sentiment expressed on this subject by Hippocrates, Cullen, and Callisen. The next is not so: it is mentioned by Sir James Macgrigor, that in the march of the guards through Gallicia, one of them was attacked with tetanus, in consequence of a slight wound of the finger. As it was impossible to think of leaving the man in the wretched village where he was taken ill, he was carried on a bullock car, in the rear of the battalion. During the first part of the day he was drenched with rain, the thermometer standing at 32°; but, after ascending one of the highest mountains in Gallicia, the patient was in a cold of 30°; and he was exposed from six in the morning to ten at night, when he was found half starved to death, but free from every symptom of tetanus.—(See *Med. Chir. Trans. vol.* 6, *p.* 450.)

Mr. Abernethy, in his lectures, expresses his conviction, that in tetanus and all nervous affections, it is a most material point to operate on the brain, through the medium of the digestive organs, and that the production of secretions from the alimentary canal has a more beneficial effect than any other means. He particularly commends the exhibition of calomel and jalap, mixed with treacle, as answering better than salts. Where much difficulty occurs in making the patient swallow common purgative medicines, I would strongly recommend to the recollection of practitioners, the oleum tiglii, a drop of which, blended with a little mucilage, and put on the root of the tongue, will operate powerfully on the bowels.

Another remedy said to have frequently effected a cure in tetanus is mercury.—(See *Journ. de Med. p.* 45.) Mercurial frictions, practised so as to bring on a quick affection of the mouth, and in an early stage of the disorder, are preferred. Others contend, that it matters not whether mercury be rubbed into the body or given internally. It is generally allowed that opium may be advantageously exhibited at the same time. This practice was first adopted in the West Indies (see *Edinb. Physical and Literary Essays, vol.* 3), where it succeeded in many cases. Whatever benefit, however, may have been experienced from this plan in mild cases, it completely fails in the acute form of the disease. Mercurial frictions appeared to Baron Larrey to aggravate the symptoms, in the cases where the plan was tried in Egypt (*Mém. de Chir. Mil. t.* 1, *p.* 257); and Dr. Emery, Mr. Guthrie, and other medical officers attached to our army in the Peninsula, tried inunction of the whole body, three times a day, with strong mercurial ointment in unlimited quantity, with no degree of success. After the battle of Toulouse, a fatal case even occurred in a man strongly under the influence of mercury, which he had been previously using for the cure of the itch.—(*Sir J. Macgrigor, in Med. Chir. Trans. vol.* 6, *p* 454.) The submuriate of mercury, combined with Ipecacuanha, also proved inefficacious in acute cases; but in chronic ones it proves serviceable by keeping open the bowels.

Another method of treating tetanus is that of administering the most powerful tonics and stimulants, such as wine, brandy, ether, preparations of ammonia, bark, cordials, &c. The introduction of this plan was chiefly owing to the eminent Dr. Rush, Professor of Medicine in Philadelphia, who published in the Trans. of the American Philos. Society, vol. 2, a paper entitled "*Obs. on the Cause and Cure of Tetanus.*" Dr. Rush considers tetanus as a disease essentially connected with debility, and he recommends for it the exhibition of the preceding class of remedies. He particularly advises the liberal use of wine and Peruvian bark; and as we have already stated, when tetanus arises from a wound, he directs the dilatation of it, and dressings with oil of turpentine. Considerable success is represented as having attended the practice. Several other instances of success are also recorded by Dr. Hosack.—(*American Medical Repository, vol.* 3.)

Dr. Elliotson, considering neuralgia, paralysis, agitans, chorea, and tetanus to be "affections of the nerves, or of those parts of the brain and spinal marrow which are immediately connected with them," was induced to try the effect of subcarbonate of iron in three examples of traumatic tetanus, in consequence of the success with which it had been exhibited in the other complaints above specified. Costiveness he obviated by giving ʒ ij. of the ol. terebinthinæ, followed, when requisite, by the ol. ricini. The subcarbonate of iron was given in large frequent doses of ʒ ij., and even half an ounce, every two hours. It was mixed with twice its quantity of treacle; and blended with strong beef-tea. Two of the cases recovered; the third, which was one where the spasms were excessively violent, and the pulse 140, was too rapid in its progress for an effectual trial of the remedy, the patient dying the day after the commencement of the plan.—(See *Med. Chir. Trans. vol.* 15, *p.* 161, *&c.*) As traumatic tetanus has been occasionally cured under a variety of plans of treatment, it is difficult to draw any certain inference respecting the real utility of the subcarbonate of iron in this disorder, from the two examples of recovery published by Dr. Elliotson.

Nothing is a more certain proof of our not being acquainted with any very effectual method of treating a disease than a multiplicity of remedies which are as opposite as possible in their effects. We have seen that the celebrated Dr. Rush conceived, that tetanus was a disease connected with debility; and he has recorded examples in which it was successfully treated by tonics and stimulants. Extraordinary, however, as it may appear, many practitioners are advocates for venesection, especially in the early stage of tetanus. Dr. Dickson thinks that in a full habit, where the wound is swelled, inflamed, and painful, venesection, with free purging and such other means as are calculated to allay the general and local irritation, affords the fairest chance of averting the danger.—(See *Med. Chir. Trans. vol.* 7, *part* 2.) Larrey has also published several cases in which bleeding had a good effect. We are informed by Sir James Macgrigor, that in our military hospitals in Spain venesection had a fair trial. In three cases at St. Andero, detailed by Mr. Guthrie, this was the principal remedy. One patient with tetanus, from a wound of the back part of the hand, was bled nearly *ad deliquium* several times with good effect, calomel and diaphoretics being also given, and he recovered. Another patient was bled in the same manner with such amendment, that he suffered but little from spasm, and could open his mouth very well, when he was seized with diarrhœa, which, in his debilitated state, carried him off. In the third case, which was one of acute tetanus, venesection, pushed to the utmost, totally failed.—(*Op. cit vol.* 6, *p.* 455, 456.)

The powerfully relaxing effects of tobacco clysters, in cases of hernia and enteritis, have suggested a trial of them in tetanus. In one very acute case, the plan was tried by Mr. Earle, but it only afforded a temporary alleviation of the spasms, and as it caused severe agitation, it was discontinued. According to Sir James Macgrigor, tobacco clysters tried in the advanced stage of the disease seemed to have no effect. He considers, however, the tobacco fume as deserving farther trial.

A remarkable case is recorded by Dr. Phillips, in which the jaw suddenly fell, upon the exhibition of an enema with oil of turpentine.—(See *Med. Chir Trans. vol* 6, *p* 65.)

According to Baron Larrey, frictions with oily liniments, as recommended by some authors, were tried by the French surgeons at Cairo; but they produced no change in the state of the disease. We learn from the same authority, that the application of blisters to the throat also failed in checking the symptoms.

The Barbadoes tar, mentioned by Cullen, electricity, the colchicum autumnale, or meadow saffron, recommended by Dufresnoy, and several other means formerly in repute for their virtues in cases of tetanus, have now been fully proved by experience to possess little or no claim to this character.

[Perhaps there is no disease which has been treated by so great a variety, and even contrariety of remedies as *tetanus*. There are in America very many surgeons who pursue the stimulating plan of Dr. Rush; among these is Professor Hosack, who relies upon Madeira wine: while there are many others who adopt the opposite theory, and not only bleed unsparingly, but combine the whole antiphlogistic battery; and instances of their success are reported, quite as numerous as those of the opposite theory and practice. The liberal use of mercury, in large and oft-repeated doses, has found many advocates, and many cures have been reported in which this was the only agent employed.

Of late, however, the treatment of this disease in this country has very much changed, and extensive vesication, especially on the region of the spine, seems so be very generally relied on, and with singular success. One of the most severe cases of tetanus I ever witnessed arose from a gun-shot wound, a load of shot having entered the back and penetrated into the dorsal and lumbar vertebræ. The disease speedily assumed the form of opisthotonos, and was treated by the application of the caustic potash to the spine, from the cervical vertebræ to the sacrum. About an inch in width of the skin was destroyed all the way down, and the only internal medicines relied upon were, prussic acid in large doses, and elaterium as a cathartic. This case and its successful issue was reported in the Medical Recorder for 1825. The prussic acid was given at the suggestion of my friend Professor Pattison, now of the London University, who informed me that he had seen it of great value in the treatment of every form of tetanus. I was inclined to attribute the removal of the disease to the effect of the caustic application, as the irritation and eschar were considerable, and relief almost immediate. Similar results are reported as having followed extensive blistering with cantharides along the course of the spinal marrow, and this practice is now becoming very general in America.—*Reese.*]

THORAX, WOUNDS OF. See *Wounds of the Thorax*

THROAT, WOUNDS OF. Injuries of this kind are often attended with considerable danger, on account of the great number of important parts which are interested; but mere cuts of the integuments of the throat and neck are not (generally speaking) dangerous cases, and do not materially differ from common incised wounds of the skin in any other part of the body. They are not liable to be followed by any particular consequences, and require the same kind of treatment as cuts in general.—(See *Wounds—Incised Wounds.*)

In wounds of the throat and neck, however, the larynx and trachea, pharynx and œsophagus, the trunk of the carotid artery, and all the principal branches of the external carotid, the large jugular vein, the eighth pair of nerves, and the recurrent nerve are all exposed to injury; some much more so than others, but all of them being occasionally reached by the edge of the knife or razor, or the point of the sword or other instruments.

It would be absurdity to offer an account of what is to be done in cases attended with some part of the mischief above pointed out; for no patient thus wounded, would ever be found alive. Wounds of the eighth pair of nerves are generally considered fatal, though some doubts begin to be entertained on the point. Indeed, Klein positively states that such an injury is not fatal.—(See *Journ. der Chir. b.* 1, *p.* 123, 8*vo. Berlin*, 1820.) However, if the wound of one of these nerves be not absolutely fatal, there can be no doubt of its being highly perilous, and that it should be most cautiously avoided. The nerve, as is well known, proceeds down the neck, in the same sheath of cellular substance which includes the carotid artery, and lies on the outside of this vessel, between it and the internal jugular vein.

Wounds either of the carotid artery or internal jugular vein must generally prove immediately fatal, in consequence of the great and sudden loss of blood. However, were any surgeon on the spot at the moment, he should instantly secure the wounded vessel. In tying the carotid one caution is highly necessary, viz. always to be sure that the par vagum is excluded from the ligature; for were this nerve to be tied, the mistake, if not absolutely mortal, would leave but a slight possibility of recovery.

If the mouth of the vessel could not be at once secured, pressure should be instantly resorted to, for the purpose of producing a temporary suppression of the hemorrhage. The surgeon should then either make the necessary enlargement of the wound in the integuments, with a due and constant recollection of the important parts near the place, or else, in the case of the carotid being injured, he should cut down to this vessel in the manner explained in the article *Aneurism.*

In lacerated wounds, the carotid artery may be injured, and yet the patient not immediately bleed to death; for it is the nature of all wounds attended with much laceration and contusion not to bleed so freely as clean cuts. Mr. Abernethy has related a case in which the carotid and all the chief branches of it were wounded in a man who was gored in the neck with a cow's horn; yet death did not directly follow, and there was time to have recourse to the ligature. Baron Larrey even reports one or two cases in which the bleeding from the carotid, injured by a gun-shot, was permanently stopped by pressure.—(See *Mém. de Chir. Mil.*) Dr. Hennen also refers to another instance of a similar nature.—(*On Military Surgery*, *p.* 106, *ed.* 2.)

Punctured wounds might obviously injure either the carotid or the internal jugular vein, without the patient expiring of hemorrhage at once; because the smallness of the wound in the skin might hinder the fatal effusion of blood.

However, frequently, when these vessels are wounded, the par vagum is also injured, and the case is mortal, either immediately from the direct effects both of the injury of the nerve and sudden loss of blood, or very soon afterward, the bleeding being of a slower and more interrupted kind; which circumstance must depend on the lacerated nature of the wound, the small size of the opening in the vessel, or of that in the skin, &c.

Persons who attempt suicide by cutting their throats, do not often divide the carotid artery, on account of their incision being made too high up. Where the carotid arteries emerge from the chest, they are situated

by the side of the trachea, and even a little more forwards than it. However, as these vessels proceed up the neck, they become more laterally situated with respect to the windpipe; and when they have arrived at the upper part of the neck, where persons who aim at suicide almost always cut, they become situated more backwards than the trachea, inclining towards the angle of the lower jaw.

The œsophagus is so deeply situated, lying close to the bodies of the vertebræ and behind the trachea, that it is not often concerned in any incised wounds, which do not immediately prove fatal, in consequence of the division of other important parts. Yet numerous cases are recorded in which the œsophagus is said to have been wounded; and what is usually set down as a criterion of the fact, is the passage of victuals through the wound. In many of these narrations, the writers seem to have forgotten that wounds made above the os hyoides, as they frequently are, may enter the mouth, and the victuals escape through the cut, without the œsophagus or pharynx being at all concerned.

However, no doubt the œsophagus has occasionally been wounded, together with the trachea, not only without the patient perishing so immediately as to be incapable of receiving any succour, but without every chance of recovery being destroyed. Stabs and gunshot wounds may injure the œsophagus, and leave all other important parts untouched. Nay, when other parts of consequence are injured, the patient is sometimes saved.—(See *Hennen's Military Surgery*, *p.* 363, *ed.* 2.)

Even where the œsophagus is known to be wounded, its deep situation would prohibit us from doing any thing to the breach of continuity in the tube itself. The best plan would be to have recourse to antiphlogistic means, and to introduce a flexible elastic gum catheter, from one of the nostrils down the œsophagus, for the purpose of conveying nourishment and medicines into the stomach, without any risk of their passing out at the wound. An instrument of this kind will lie in the above situation for any length of time without occasioning much inconvenience; and besides being advantageous for injecting nourishment and medicines down the passage, and keeping them from issuing at the wound, it prevents all necessity for the wounded œsophagus to act, and become disturbed, when there is occasion to take any kind of liquids, whether in the way of medicine or food. The outer wound should be brought together and treated on common principles.

When persons cut their throats as I have explained, they do not often divide the carotid artery, owing to their incision being usually made high up in the neck, where this vessel has attained a very backward situation. When any serious hemorrhage does arise, it is sometimes from the lower branches of the lingual artery, but most frequently from the superior thyroideal arteries. Such arteries may occasion a fatal bleeding, which, indeed, would more frequently be the event than it actually is, did not the patient often faint, in which state the bleeding spontaneously ceases, and gives time for the arrival of surgical assistance.

I need hardly tell the reader that these arteries are to be tied, and that this important object is the first to which the surgeon should direct his attention. The danger of bleeding to death being obviated as soon as possible, the other requisite measures may be more deliberately executed.

With respect to wounds of the trachea, the same plan of conveying food and medicines into the stomach through an elastic gum catheter, introduced from one of the nostrils down the œsophagus, is highly proper, though too much neglected; for nothing creates such disturbance of the wound as the convulsive elevation and depression of the larynx and trachea, which are naturally attendant on the act of swallowing.

When the trachea is cut, the patient's power of forming the voice is more or less impaired, in consequence of the air passing into and out of the lungs chiefly through the wound. Besides air, a considerable quantity of the natural mucus of the trachea is also continually coming out of the wound.

The grand means of accomplishing the union of wounds of the trachea, are a proper position of the head, and a rigorous observance of quietude. By raising the patient's head with pillows, and keeping his chin close to his breast, the edge of the wound both in the skin and trachea, are placed in contact, even without any other assistance, unless the division of the trachea be exceedingly large. It is proper, however, to promote the effect of a suitable position with strips of sticking plaster, and sometimes with a suture or two. But the necessity for sutures must depend on the extent of the division of the trachea; for unless most of the circle of this tube be cut, and position be neglected, the wound in it will not gape. The stitches should never be passed through the lining of the trachea, as this method would be likely to make it inflame, and occasion considerable coughing and irritation, attended with very pernicious effects.

Should there be much coughing, apparently arising from irritation and inflammation in the trachea, bleeding is proper, if other considerations do not forbid it. The spermaceti mixture with opium is also frequently of great service. I never saw a wound of the trachea unite by the first intention.

[That wounds of the trachea do unite by the first intention would seem to be rendered probable, at least, by the early recovery of patients after the operation of bronchotomy. This operation is now very frequently performed in this country, for the removal of foreign bodies from the trachea and sometimes for trachitis or croup. Indeed I have known it resorted to dernierly in phthisis trachealis, but without benefit. The fact however is sufficiently established, that the operation is seldom followed by any troublesome symptoms, and the trachea does unite in a very few days.

In this operation it is true that the incision is often perpendicular only, and the crucial incision is not always necessary, while in wounds of the throat as in attempted suicides, the trachea is generally wounded across its caliber or between the rings. I remember seeing one instance in which a man cut his throat with a razor, and divided the trachea entirely across and yet it united again by the treatment recommended by Mr. Cooper, and in a few weeks his voice and respiration had entirely recovered. We should always make the attempt as here advised, and will very generally be successful.—*Reese.*]

See *John Bell on Wounds*, *ed.* 3. *Hennen's Military Surgery*, *p.* 356, *&c. ed.* 2, 8*vo. Edin.* 1820. *Among other references made by Dr. Hennen, the following seem to me to merit particular notice:—An interesting case of wound of the neck, succeeded by hemiplegia, and another of gun-shot wound of the throat, succeeded by paralysis and convulsions, says Dr. Hennen, is given by Forestus in his Surgical Observations. Another with loss of motion in the arm, from a wound in the neck, is to be found in the Edin. Med. Essays, vol.* 1. *And in the Med. Commentaries, by Dr. Duncan, vol.* 4, *p.* 434, *and vol.* 8, *p.* 356, *are two interesting cases. Murcinna, in his Med. Chir. Beobachtungen, relates a case of removal of the thyroid gland by a cannon-ball; the patient survived fourteen days, and died of dysentery. Wounds of the œsophagus often remain open for indeterminate periods, as is exemplified in a case reported by Trioen, in his Fasciculus Observationum, Lugd.* 1745, *p.* 40. *Mr. Bruce has recorded an interesting case of wound of the Œsophagus, in Med. Chir. Journ. vol.* 1, *p.* 369. *I would also refer to various parts of Mém. de Chir. Milit. by Baron Larrey; and Thomson's Report of Obs. made in Mil. Hospitals in Belgium*, 8*vo. Edin.* 1816.

THROMBUS. (From θρόμβος, coagulated blood.) A clot of blood. The term is also applied to a tumour, formed by a collection of extravasated coagulated blood, under the integuments after bleeding. When not considerable it is usually called an *cochymosis.*—(See this word and *Bleeding.*)

A thrombus after bleeding generally arises from the opening in the vein not corresponding to that in the skin. The patient's altering the posture of his arm, while the blood is flowing into the basin, will often cause an interruption to the escape of the fluid from the external orifice of the puncture; and consequently it insinuates itself into the cellular substance in the vicinity of the opening in the vein. In proportion as the blood issues from the vessel, it is effused in the cellular membrane, between the skin and fascia, covering the muscles; and this with more or less rapidity, and in a greater or less quantity, according as the edges of the skin more or less impede the outward escape of the fluid. Sometimes, also, a thrombus forms

after venesection, when the usual dressings, compress, and bandage have been put over the puncture, and the patient imprudently makes use of the arm on which the operation has been done. This is more particularly liable to happen when the opening in the vein has been made large.

When the extravasation is not copious, it is of little importance, for the tumour generally admits of being easily resolved, by applying linen dipped in any discutient lotion. If the swelling be more extensive, applying to it a compress, wet with a solution of common sea-salt, is deemed an efficacious plan of promoting the absorption of the extravasated blood. Brandy and a solution of the muriate of ammonia in vinegar, are likewise eligible applications.

It sometimes happens that a thrombus induces inflammation and suppuration of the edges of the puncture. The treatment is now like that of any little abscess: a common linseed poultice may be applied, and any considerable accumulation of matter should be prevented by making an opening with a lancet in proper time. As soon as the inflammatory symptoms have ceased, discutients should be employed again for the purpose of dispersing the remaining clots of blood, and surrounding induration.

When the quantity of blood is large, many authors recommend opening the tumour at once; and despairing of the power of the absorbents to remove the extravasation, they direct as much of the blood as possible to be pressed out through the incision. I believe, however, that making an opening is seldom necessary, and often brings on inflammation and suppuration, when they might be avoided. I have never seen any case in which this practice seemed necessary, though such a case may be conceived.

THYROID GLAND, DISEASED. See *Bronchocele.*

THYROID GLAND, EXTIRPATION OF. That such an operation, though attended with great difficulties, is not impracticable, is proved by the following example:—

On the 20th of March, 1791, a woman presented herself for admission at the Hôtel Dieu, with a tumour of the right portion of the thyroid gland. The swelling was two inches in diameter, round, hard, and attached to the right and middle part of the trachea, and it pushed outwards the sterno-mastoideus muscle. Independently of its being sensibly raised by each pulsation of the arteries, it followed the motions of deglutition, and in a slight degree impeded the passage of solid aliment. Desault made an incision through the middle of the tumour, beginning one inch above, and finishing one inch below the swelling. By the first stroke he cut down as far as the gland, dividing the integuments, the platysmamyoides, and some fibres of the sterno-hyoidei and sterno-thyroidei muscles. An assistant, with the view of fixing the tumour, drew it towards the inner edge of the wound, while the operator detached the swelling from the sterno-mastoideus muscle. In dissecting the cellular substance which united the parts, two small arteries were divided, which were secured with ligatures. The outer portion of the tumour being thus disengaged, the inner was detached in the same way. The tumour was then drawn outwards by means of a hook, that it might be separated with more ease from the trachea. In the course of this dissection, the branches of the thyroid arteries were successively tied as fast as they were divided. The assistant who held the hook pulled the gland from within and forwards, while the surgeon finished the dissection outwards and from above downwards. This part of the operation was most difficult: it was necessary continually to wipe away the blood with a sponge, which necessarily prevented the parts from being easily distinguished, and obliged the surgeon to cut but a little at a time, and always to examine well with his finger those parts which he was about to cut. By this cautious dissection, the superior and inferior thyroid arteries were laid bare, and afterward tied with the aid of a blunt crooked needle. They were then transversely divided, and the remaining part of the tumour detached from the trachea, to which it strongly adhered. The wound resulting from this operation was nearly three inches in depth; outwardly bounded by the sterno-mastoideus muscle, inwardly by the trachea and œsophagus, and posteriorly by the carotid artery and par vagum, which were exposed at the bottom of the wound. The extirpated tumour was five inches in circumference; and on examination was found to differ in no particular from scirrhous glands, except that in the centre there was a cartilaginous nucleus. The patient left the hospital perfectly well the thirty-fourth day after the operation.—(See *Desault's Parisian Chir. Journ. vol.* 2, *p.* 292. 296.)

The extirpation of the thyroid gland is an operation extremely difficult, and certainly highly dangerous, when performed by an operator but moderately exercised in the practice of his profession. The number and size of the arteries divided, the proximity of the trachea, œsophagus, jugular vein, and carotid, near which the knife must necessarily pass, are the principal dangers which have deterred the majority of practitioners from performing the operation. The first time that Gooch undertook the operation, he was deterred from finishing it by the hemorrhage, and his patient died on the eighth day. The second time he succeeded better, but was incapable of securing the vessels; and the hemorrhage, which would have been mortal, was only stopped by the pressure of the hands of assistants for the space of eight days.—(*Gooch's Med. and Chir. Obs. p.* 130. *Bell's System of Surgery, vol.* 5, *p.* 525. *Richter's Bibl. t.* 2, *p.* 128.)

Vogel and Theden also did the operation with success; but no surgeon who has attempted this bold operation has signalized himself so much by it as Dr. Hedenus, of Dresden, who has removed the diseased thyroid gland in six instances with success. His reasons for resorting so often to this difficult operation, he says, are: 1st, because he has seen a patient with enlarged thyroid gland, for which the seton had been employed, seized on the ninth day with violent tetanus, which proved fatal in 17 hours; 2dly, because he considers setons and other similar means unlikely to do good, as he has almost always found portions of cartilage or bone within the diseased part. In one of his cases the gland was as large as a skittle-ball; it covered the whole of the front of the neck, reaching from the os hyoides to the upper part of the sternum, and pushing back on each side the sterno-cleido-mastoideus and adjacent parts. The circumference of its base was 14 inches, and its transverse diameter seven. It had a firm, tense, heavy feel. The skin was full of enlarged veins; and the tumour communicated to the hand a throbbing motion, which might have been taken for that of an aneurismal swelling.

The patient was laid on a mattress. Dr. Hedenus then divided the skin in a longitudinal direction, from the os hyoides to the top of the sternum, and dissected and turned back the skin and platysma myoides on each side to the extent of two inches. The sterno-hyoid and sterno-thyroid muscles were then seen firmly adherent to the whole tumour. An attempt was made to separate them from the swelling; but scarcely had the dissection extended a quarter of an inch, when a copious stream of blood proceeded from numerous small arteries, which could neither be tied, on account of their minuteness, nor stopped with styptics. Hedenus, therefore, determined immediately to cut through the above-named muscles at their points of attachment above and below, and to remove the intervening portions with the tumour.

Respecting this part of the operation, it merits particular notice, that, after the cure, the motions of the os hyoides and larynx, and the functions of respiration, speech, and deglutition all remained unimpaired; which was also the case in four other instances, in which Hedenus removed portions of the sterno-hyoidei and sterno-thyroidei muscles.

Hedenus next separated the swelling above and below, from the sterno-cleido-mastoid and omo-hyoid muscles, and also from the jugular vein and carotid arteries, to which it was closely adherent, until he had freed it as far as the point where the thyroid arteries originate. He then tied all the superior and inferior thyroideal arteries close to the tumour, and, on account of the free anastomoses, applied to each vessel two ligatures, and divided it in the interspace. The more deeply the dissection now reached, the more hazardous did the operation appear, as at every cut of four or five lines he was obliged to tie two or three arteries which was done with great difficulty. After most cautiously dissecting to the base of the tumour, which was firmly attached to the thyroid cartilage, and the three upper rings of the trachea, he met with so many

arteries, for the most part as large as the radial or digital, that in order to prevent farther loss of blood, he decided to tie the base of the swelling, and then cut away the tumour above the ligature. For this purpose he used a blunt-pointed aneurismal needle, armed with two four-threaded ligatures. This was passed through the middle of the base, while the tumour was pulled upwards; and one ligature was then firmly tied over the lower, and the other over the upper half of the base. For the sake of being still more sure of commanding the hemorrhage, Hedenus also applied a third ligature all round the swelling, and he then extirpated the diseased gland, without any bleeding from the part included in the ligatures. These were now fastened at the sides of the wound with adhesive plaster. The whole surface of the wound was sprinkled with powdered gum arabic, over which was laid agaric, wet with Theden's vulnerary lotion. These applications having been covered with charpie, the lips of the wound were drawn towards each other with adhesive plaster, which was also covered with compresses wet with vinegar, and renewed every six or eight minutes.

It is quite unnecessary for me to follow the narrative of this case in all its details. The patient, between the period of the operation and that of his cure, suffered a great deal of indisposition, which at first chiefly consisted of difficult deglutition, severe pain all over the right side of the head, imperfect use of the arm, frequent cough, and hoarseness. In the afternoon blood began to flow through the bandage, and, as the bleeding had not abated after an hour's pressure with the hand, the dressings were removed, and the blood found to proceed not from any particular artery, but from all the wounded surface. The wound was again sprinkled with gum arabic, which was covered with sponge and a bandage: two surgeons were also directed to keep up pressure with their hands. The day after the operation the febrile symptoms ran high, but in two days subsided again. On the eighth day all the ligatures came away, even that which had encircled the tumour, and a large quantity of fetid matter was discharged. Soon afterward a considerable bleeding arose, which however was stopped with sponge and alum powder. On the 16th day another serious hemorrhage was occasioned by a convulsive cough, and life was endangered by the loss of not less than two pounds of blood. The bleeding which came from the upper angle of the wound was stopped by means of a piece of sponge dipped in rectified spirit, and covering the wound and indeed the whole neck with compresses wet with vinegar, pressure being also kept up on the sponge with the hand. The dangerous state of the patient may be conceived when it is known, that there was now a deadly paleness of his whole body, languid eyes, dimness of vision, loss of hearing and speech, and extreme prostration of the vital powers. With the aid of judicious treatment, however, he rallied, and in the end left the hospital quite cured.

In another case operated upon by Hedenus, the difficulties were even greater, owing to the extension of a portion of the right lobe of the thyroid gland as far back as the transverse processes of the cervical vertebræ; but, after the third day from the operation, the progress to recovery was not interrupted by any bleedings.—(See *Graefe's Journ. b.* 2, *p.* 237, *&c.* or *the Quarterly Journ. of Foreign Med. No.* 19.)

There can be no doubt, that the method adopted by Hedenus was well calculated to obviate the great source of immediate danger, viz. the bleeding. As long as it was practicable he took up every vessel which he exposed or divided; and when this plan could not be continued, he tied the base of the tumour ere he detached the enlarged gland from the larynx. This tying of the base of the swelling, though sometimes practised on other occasions, as in the removal of diseased axillary glands, constitutes the chief peculiarity of Hedenus's method.

A case has been published in which Klein removed a very large thyroid gland. The patient, a boy, eleven years of age, died on the operating-table.—(See *Journ. der Chir. b.* 1, *p.* 120, 8*vo. Berlin*, 1820; or *the Quarterly Journ. of Foreign Medicine, vol.* 2, *p.* 380.) On the whole, I consider that the practice of tying the thyroideal arteries is generally a safer experiment than the removal of the enlarged gland with a knife.—(See *Bronchocele, Med. Int.* 44, *p.* 363.) But now that the efficacy of the preparations of iodine, in many cases of bronchocele has been fully proved, it is to be hoped that few cases will present themselves in which either measure will be absolutely necessary.

TIC DOULOUREUX. This term is used to signify a disorder, the most prominent character of which consists in severe attacks of pain, affecting the nerves of the face; most frequently the filaments of that branch of the fifth pair which comes out of the infra-orbitary foramen: but sometimes the other branches of the fifth pair, and occasionally the numerous filaments of the portio dura of the auditory nerve, which are distributed upon the face. The complaint is not continual, but occurs in violent paroxysms, which vary in duration in different instances. It is the *trismus dolorificus* of Sauvages; the *facies morbus nervorum crucians* of Dr. S. Fothergill; and of that order of diseases which Professor Chaussier has so aptly denominated *neuralgies* (from *νεῦρον*, a nerve, and *αλγος*, pain); for it should be known that many other parts of the body are subject to a similar affection.

The first excellent description of tic douloureux was published in the year 1776, by the late Dr. Fothergill.—(See *Med. Obs. and Inq. vol.* 5.) It is not true, however, as is generally stated, that he was the first author who noticed the complaint. This, indeed, is so far from being correct, that we even find an account of an operation done long ago by Louis, for the relief of the disease (see *No.* 36 *de la Gazette Salutaire*, 1766); and this identical case actually became a subject of hot dispute between the physicians and surgeons of the French metropolis.—(See a Thesis, entitled "*Utrùm in pertinacibus capitis et faciei doloribus aliquid prodesse possit, sectio ramorum nervi quinti paris? Proponebat Viellart*, 1768, *conclusio negativa.*")

Tic douloureux conveniently admits of being divided into four species, called by the French *frontal, sub-orbitary, and maxillary neuralgia, and the neuralgia of the facial nerve.*

In the frontal neuralgia, the pain usually begins in the situation of the supra-orbitary foramen, extending at first along the branches and ramifications of the frontal nerve, distributed to the soft parts upon the cranium, and afterward shooting in the direction of the trunk of the nerve towards the bottom of the orbit. In a more advanced stage, the conjunctiva and all the surface of the eye participate in the effects of the disorder, and become affected with chronic inflammation, which is described as a particular species of ophthalmy. At length the pain passes beyond the distribution of the branches of the frontal nerve, and affects all the corresponding side of the face and head. It seems as if it extended itself to the facial, sub-orbitary, maxillary, and even to the temporal and occipital nerves, through the communications naturally existing between the filaments of all those organs of sensation. Each paroxysm produces a spasmodic contraction of the eyelids, and a copious effusion of tears.

The sub-orbitary neuralgia is first felt about the sub orbitary foramen. The seat is probably in the nerve of this name, and the pain extends to the lower eyelid, the inner canthus of the eye, the muscles about the zygoma, the buccinator, cheek in general, ala of the nose, and the upper lip. At a later period, the pain appears to extend backwards to the trunk of the nerve, and those branches which are given off in its passage through the sub-orbitary canal. Hence, pains are then experienced in the upper teeth, the zygomatic fossa, the palate, tongue, and within the cavity of the nose. As the disorder advances, it may extend, like other neuralgiæ of the face, to all the same side of the head. During the paroxysms, when the disease is fully formed, an abundant salivation usually takes place. In general, the attendant toothache deceives the practitioner, who, in the belief that the pain arises from another cause, uselessly extracts several of the teeth.

The tic douloureux of the lower jaw or maxillary neuralgia, is usually first felt about the situation of the anterior orifice of the canalis mentalis, and it extends to the lower lip, chin, neck, teeth, and temple. This form of the complaint is more uncommon than the preceding; but after it has prevailed some time, is equally remarkable for its intensity.

With respect to the neuralgia of the facial nerve or portio dura of the auditory nerve, it is a case which very soon cannot easily be distinguished from the other species of tic douloureux. The pains at an early period are no longer confined to the passage of the principal

branches of this nerve between the parotid gland and ramus of the jaw. The numerous communications of the portio dura with the rest of the nerves of the face seem to facilitate the extension of the disease, so that the agony is soon felt over the whole side of the head. The original source of the disorder can only be detected by attentively considering the progress of the complaint in all its stages.—(See *Delpech, Traité des Maladies reputées Chirurgicales, t.* 3, *sect.* 7, *p* 214, *&c.*)

Tic douloureux may be known from rheumatism by the paroxysm being excited by the slightest touch, by the shortness of its duration, and the extreme violence of the pain. In acute rheumatism, also, there is fever, with redness, heat, and generally some degree of swelling; and in chronic rheumatism the pain is obtuse, long continued, and often increased at night; none of which symptoms characterize tic douloureux.

It may easily be distinguished from hemicrania by the pain exactly following the course of the branches of the affected nerve.

It is known from the toothache by the comparative shortness of the paroxyms; the quickness of their succession; the intervals of entire ease; the darting of the pain in the track of the particular nerve affected; the more superficial and lancinating kind of pain; and the convulsive twitchings which sometimes accompany the complaint.

The causes of tic douloureux may be said to be in general unknown; but there are a few instances recorded, which appear to be the consequence of external violence, wounds, contusions, &c. It is mentioned in one of the journals, that distant irritations, especially of the splanchnic nerves, often produce this disease, and that Sir H. Halford has met with cases where the discharge of portions of diseased bone, even from a distant part, has cured the complaint.—(*Med. Chir. Review, No.* 9, *vol.* 3.) The difficulty of placing implicit reliance on such observations depends on the fact, that disorders frequently exist together in different parts, without having any kind of connexion with each other, and terminate quite as independently.

A modern writer has related a very curious instance of a resembling disease in the arm, where the affection proceeded from the lodgement of a small bit of bullet in the radial nerve.—(*Denmark, in Med. Chir. Trans. vol.* 4, *p.* 48.) Dr. Parry attributed the pain to increased vascularity or determination of blood (perhaps amounting to inflammation) to the neurilema or vascular membranous envelope of the nerves affected.—(*Elements of Pathology and Therapeutics.*)

Sir A. Cooper states, however, in his lectures, that the nerves in this disease are certainly not in an inflamed state; for they are found of their natural colour, and rather diminished than enlarged. The latter fact was ascertained in a dissection made by Mr. Thomas. An occasional thickening of the nerve is mentioned by Larrey, Delpech, &c.; but whether from conjecture or actual observation I am uncertain.

Stimulating embrocations, blisters, caustic issues, fomentations, leeches, friction with mercurial ointment, (*Edinb. Med. and Surg. Journ. vol.* 3), electricity, opium in large doses, the arsenical solution, and a variety of antispasmodic medicines, are the principal means which have been tried; but for the most part, they only afford partial and temporary relief. Lasserre has reported two cases which were cured by bark joined with opium and sulphuric ether; and two other examples which yielded to pills composed of the extract of hyoscyamus, valerian, and peroxide of zinc.—(*Journ. Univ. des Sciences Méd. No.* 64, *Art.* 14.) Belladonna has often been tried and often failed. Two cases, in which it answered in doses of two grains and two grains and a half, were lately published by Mr. Thompson of Whitehaven.—(See *Lond. Med. Repository for July*, 1822.) M. Piedagnel cured a neuralgia of the infra-orbitary nerve, with the sulphate of quinine, ten grains of which were blended with equal portions of orange-flower water and syrup, and taken in four doses, the medicine being continued afterward in weaker doses for a short time. M. Dupré has also published various observations representing the sulphate of quinine as a very powerful remedy for neuralgia in its various forms. The testimony of Dr. Rabey is also in favour of its exhibition, and his opinion is backed by two cases in which he tried the medicine with success.—(See *Magendie's Journ. de Physiol. April*, 1822, *&c.*) An example of violent frontal neuralgia yielded to pills, containing in each one-sixth of a gr. of arsenious acid made up with soap. This case was the consequence of an injury of the os frontis —(*Journ. Complém. du Dict. des Sciences Méd. No.* 48.) From some facts published by Dr. Marcet, the extract of stramonium in doses of one-eighth and one half a grain thrice a day, seems to be sometimes capable of alleviating the distressing agony of the present disorder.—(See *Med. Chir. Trans. vol.* 7, *p.* 75, *&c.*: also *Kirby's Cases*, 8*vo. Lond.* 1819.)

In 1820, Mr. B. Hutchinson published some cases tending to prove that the subcarbonate of iron, in doses of ℈ij. or ʒj. two or three times a day, is often an excellent remedy for tic douloureux. In fact, if the sulphate of quinine be excepted, this medicine at present possesses more reputation than any other for its virtues in this complaint. It is also highly commended by Sir A. Cooper in his lectures. Yet, for the following reasons, a shrewd critic views all this praise with distrust; in all the cases, he says, the iron was taken in doses of ʒj. three times a day, for months. Two months, indeed, often elapsed before the pain, &c. were more than slightly relieved. This, he observes, is in itself almost a proof of the medicine being very inert; but when we find that Mr. Huchinson conjoins other treatment; that he takes off inflammatory action; that he attends to the abdominal functions and to the diet, and forbids mercurials, purgatives, and all medicines likely to debilitate the nervous system; we may be allowed to doubt the sole efficacy of the iron in curing these cases. Sure we are, that the majority of cases would yield in less time to the plans recommended by Mr. Abernethy for restoring the health, joined with local treatment, calculated to relieve the inflammation which in most cases, he says, probably affects the nerves themselves.—(See *Med. Intelligencer for* 1822, *p.* 472.) The latter conjecture, however, is rather repugnant to what is now commonly believed.

The strongest fact in proof of the real efficacy of the subcarbonate of iron, is mentioned by Dr. Crawford: a severe case was benefited soon after its exhibition; but by mistake, the carbonate of potass was then given for a few days, during which time the spasms returned with their usual violence and frequency: but when the iron was given again, the good effects formerly experienced from it returned.—(See *Med. and Phys. Journ. for Feb.* 1823.)

The operation of dividing the trunk of the affected nerve, and even of dissecting out a portion of it, so as to prevent all chance of a relapse from the reunion of the ends of the nerve, is a plan which has sometimes been practised with permanent benefit. Thus, any one of the three branches of the fifth pair of nerves may be divided at the point where it comes out upon the face. But before having recourse to this means, the surgeon should be sure that the particular nerve which he is about to expose and divide is really the principal seat of the disease; for when all the nerves of the face generally are affected, or when the branches of the portio dura are especially concerned, there is little hope of success. In fact, it must be confessed, that the operation has had many failures and relapses, either from the cases not having been duly discriminated, or from the neglect to remove a portion of the exposed nerve. Richerand, Delpech, and most of the leading surgeons in France, express their preference to the application of the moxa or cautery, which, they say, proves more frequently successful than the knife. This should be done directly over the apertures from which the nerves emerge on the forehead, cheek, or chin; and Richerand asserts, that by such treatment, the pains may always be cured, or at all events rendered supportable.—(*Nosogr. Chir. t.* 2, *p.* 216, *edit.* 4.) Delpech also affirms that the section of the nerve very often fails, and that issues and the repeated use of the cautery have been attended with the greatest success.—(See *Précis des Mal. Chir. t.* 3, *p.* 213.) The disfigurement of the countenance by burning applications must, however, be very objectionable; and as I think there is no positive evidence of the superiority of this method over the use of the knife, I consider what Richerand and Delpech have stated only as another instance of the extreme partiality of the French surgeons to the moxa and cauterization. Delpech confesses, however, that when the pains seem to be the consequence of a ganglion or thickening of a part

or a nerve, the excision of such part is indispensable. There can be little doubt that this would have been more proper than amputation, in Mr. Denmark's case, to which I have already referred. The theories of Dr. Parry, senior, who was generally inclined to refer the effects of disease to increased determination of blood to the parts affected, led him to believe that the operation of cutting the nerve, as performed by Dr. Haighton and others, did good rather by the division of the artificial branch supplying the affected ramification of the trigeminus nerve, than by the division of that ramification itself.—(*Parry, Elements of Pathology, &c.*)

There have been many examples of tic douloureux, which, after resisting all attempts to cure them, have been left to themselves, and after a long time, spontaneously subsided.—(*Delpech, Traité des Maladies Chir. t.* 3, *p.* 212. 215.) This author has seen the operation of dividing the chief branches of the portio dura, in front of the parotid gland undertaken, and even a portion of the soft parts cut away; but without any favourable consequences.—(*P.* 218.)

When the infra-orbitary nerve is to be divided, Sir A. Cooper recommends it to be done a quarter of an inch below the orbit. The supra-orbitary nerve should be cut through just where it passes out of the supra-orbitary foramen. An instance in which this measure produced an immediate alteration in the seat of the pain, may be read in the 8th No. of the Quarterly Journal of Foreign Med.; but the cure was not complete till the integuments had been divided from the root of the nose to the temple. The method of dividing the inferior maxillary nerve advised by the same surgeon, is to cut down to the foramen mentale on the inside of the lip directly under the bicuspid tooth. By the division of this nerve, M. Bouillard effectually cured one very severe case.—(See *Lond. Med. Repository, No.* 79.)

[Dr. Mott has adopted the practice of dividing the nerve in almost every case of neuralgia, where it is practicable. He has repeated this operation on the infra-obitary, mental, and other nerves so frequently and with so great success, that he confidently recommends it to his pupils and patients. He sometimes insulates a portion of the nerve by repeated incisions through it at small distances from each other, preferring this to the removal of a portion of the nerve, as recommended and practised by others.

My own experience leads me to believe that in those cases, in which the division of the nerve, by the knife, the insulation or removal of portions of it, all fail of success, that we have a remedy in the potass. pur. vel lapis inferalis, which will seldom, if ever, fail. I have several times cured the disease in its worst form in the pes anserinus, and in the infra-orbitary nerve, by applying this vegetable caustic until it acted upon the nerve. Stramonium and the tincture of iodine have justly obtained reputation as internal remedies in this disease.

Professor Hosack has published among his medical essays some valuable observations on tic douloureux, in which he contends that neuralgia is not a local affection or disease of a particular nerve, and to be removed by the division of such nerve; but a disease dependent upon the whole system, and only to be counteracted by remedies addressed to the peculiar state or condition of the constitution.—*Reese.*]

I have already stated, that the nerves of the extremities are subject to affections very analogous to tic douloureux. The following instance, related by Mr. Abernethy, will be found interesting:—

A lady became gradually affected with a painful state of the integuments under, and adjoining to, the inner edge of the nail of the ring-finger of the left hand. No injury to the part was remembered, which could have brought on this disease. The pain occurred at irregular intervals, and was extremely severe during the time of its continuance, which was for a day or two, when it usually abated. Accidental slight injuries always produced great pain, and frequently brought on the paroxysms, which, however, occasionally occurred spontaneously, or without any evident exciting cause. In all these particulars, the disease correctly resembled tic douloureux. As the pain increased, the disorder seemed to extend up the nerves of the arm. After the patient had endured this painful affliction for seven years, she submitted to have the skin, which was the original seat of the disorder, burnt with caustic. This application gave her intense pain, and, on the healing of the wound, she found her sufferings rather augmented than diminished by the experiment. After four years more of suffering, she consulted Mr. Abernethy, when the circumstances of the case were such as to render an operation indispensably necessary. The pain of the part was intolerable, and it extended all up the nerves of the arm; and this general pain was so constant during the night as to deprive the patient of rest. The muscles of the back of the neck were occasionally affected with spasms. The integuments of the affected arm were much hotter than those of the opposite arm, and sometimes the temperature was so increased as to cause a burning sensation in them. Under these circumstances, Mr. Abernethy did not hesitate to divide the nerve of the finger from which all this disorder seemed to originate. He laid it bare by a longitudinal incision of about three quarters of an inch in length, from the second joint of the finger, and divided it opposite to that joint, by a curved sharp-pointed bistoury, which was conveyed under it. He then took hold of the nerve with a pair of forceps, and reflecting it downwards, removed a portion it, half an inch in length, so that the possibility of a quick re-union might be prevented. The wound was brought together with sticking plaster, and it united by adhesion; but the upper part of the wound, opposite to the upper end of the nerves, became slightly inflammed and was very painful. However, in the course of three weeks, the appearance of inflammation gradually went off. After the operation, Mr. Abernethy pinched the originally affected integuments sharply with his nails, without causing any sensation; but if, in so doing, he moved the finger, then pain was felt.

The result was, that nine months after the operation, the general pains in the nerves had become very trivial: but the sensation in the integuments at the end of the finger had gradually increased, and the skin had now its natural sensibility, so as accurately to distinguish the tangible properties of any body applied to it. If, also, the originally affected part was slightly compressed, painful sensations, resembling those which formerly occurred, took place.—(*Abernethy's Surgical Works, vol.* 2, *p.* 203.) In a case resembling the former, but the consequence of a wound of the finger, Mr. Lawrence also cut down to the nerve and removed a portion of it with permanent success. In a case of severe pain in the thumb, extending up the arm to the neck, and causing a distortion of the neck, fits, &c., Sir A. Cooper cut down upon the radial nerve, by the side of the flexor carpi radialis longus, and cut out about five-eighths of an inch of it. The result was a complete cure.—(*Lancet, vol.* 3, *p.* 113.) *Fothergill's Paper in vol.* 5, *of the Medical Obs. and Inq. Dr. Haighton's Obs. in the Med. Records and Researches. Darwin's Zoonomia. TINCTURA CANTHARIDIS. Sometimes employed in gleets, and incontinence of urine, arising from a want of proper action in the sphincter vesicæ muscle. The usual dose is from ten to forty drops, twice or thrice a day; but its effects should be carefully watched; for it is apt to occasion dangerous inflammations of the urinary organs, violent stranguries, and retention of urine. It is occasionally added to various

liniments, when the object is to stimulate the skin considerably and rouse the action of the nerves and absorbents, as in certain cases of ptosis, paralysis, &c. Dr. Anthony Todd Thomson found it a useful application in the mortification of the extremities, sometimes happening without any apparent cause; and also to frostbitten parts.—(*London Dispensatory, p.* 658, *ed.* 2.)

[The tincture of cantharides has long been in use, even internally, but its value as a remedy in many cases where tonics and excitants are indicated, has but recently become well established, and for its free administration for these purposes we are more especially indebted to Roberton of Edinburgh. In cases of long protracted seminal weakness, in gleet, in leucorrhœa, and in various affections of the bladder, its value must not be overlooked. Mr. Roberton has given us his experience that it may be deemed almost a specific in leucorrhœa, but the results of the practice of our American physicians do not coincide with those of this intrepid prescriber in this disease. And when we consider the various causes upon which leucorrhœa may depend, we are not to wonder at its failure in so embarrassing a malady. That this disorder does, however, frequently yield to this prescription, we have many cases to prove. It is, however, especially in protracted gleets, in seminal weakness, and in impotency, that the remedy is found most available, and the extent to which it may be given without inducing those direful effects which some have attributed to it deserves to be recorded. The usual dose to begin with is about twenty or thirty drops three times a day; this quantity may be gradually increased, after a few days, to a drachm three times a day, and often to the extent of two drachms, as often repeated. It has been administered to a much larger amount, and with perfect safety, in the hands of Professor Francis, of New-York, by whom this practice to a great extent has been adopted. It is, however, to be borne in mind, that the beneficial effects of the lytta are best secured by persisting for a considerable while in the use of the remedy in moderate doses, rather than by excessively large ones. "In no instance," says Dr. F., "have I found those evils to ensue from its use which some have affirmed to be a consequence of it, and I believe that I have administered it more freely, and to a greater extent, than any prescriber with whom I am acquainted. In seminal weakness, and in impotency, it cannot be too highly prized. In some cases entire restoration has been effected by the cantharides, in conjunction with other tonics, adapted to existing circumstances, within the course of two or three months; in other instances, the remedy has been administered for some two years and upwards, yet with the happiest results."—*Reese.*]

TINCTURA FERRI MURIATIS has sometimes been exhibited in gleets; but a more important use was assigned to it by Mr. Cline, who ordered it in dysuria from *stricture*, in the dose of ten drops every twenty or thirty minutes, until nausea is excited. Where chalybeates are indicated, this preparation is one much approved.

"Mr. Justamond's liquid for external use in cancers, and which the original inventor called his *panacea anticancrosa*, partook considerably of the nature of this tincture, which, indeed, with an equal quantity of spirit of wine, was sometimes substituted for it.

"Lastly, it is remarkably efficacious in destroying venereal or other warts, either used alone or diluted with a small proportion of water."—(*Pharm. Chir.*)

TINCTURA IODINÆ. Take of alcohol, 7 dr. 52 gr. troy; iodine, gr. 39 1-3 troy: dose, 10 drops three times a day in a little sweetened water: used in bronchocele and cases of scrofula.—(See also IODINE, and *Magendie's Formulary, 2d edit. translated, p.* 35. The dose should be gradually increased, if necessary, to 25 or 30 minims thrice a day.

TINCTURA THEBAICA. See *Vinum Opii.*

TINEA CAPITIS. See *Porrigo.*

TOBACCO is used for promoting the reduction of strangulated hernia, either in the form of a fluid clyster, or of smoke, which latter is introduced up the rectum by means of an apparatus. Excepting the operation, the power of tobacco, particularly when assisted by the topical application of cold to the tumour, is most to be depended upon for the bringing about the return of the protruded viscera.—(See *Hernia* and *Enema.*) Tobacco clysters have also been tried with advantage in traumatic tetanus (*O'Beirne, in Dublin Hospital Reports*;) and Mr. Earle found tobacco clysters very efficacious in certain cases of retention of urine.—(See *Tetanus*, and *Urine, Retention of.*) Consult *T. Fowler, Medical Reports of the Effects of Tobacco*, 8vo. *Lond.* 1785. *A. P. Wilson, an Experimental Essay on the Manner in which Opium and Tobacco act on the living animal Body*, 8vo. *Edinb.* 1795. *R Hamilton, De Nicotianæ Viribus in Medicina, &c.* 8vo. *Edinb.* 1780.

TONGUE, DISEASES OF. This part is subject to various diseases, as ulcers, tumours, and such enlargements as sometimes cause imminent danger of suffocation.

It is correctly noticed by Mr. Earle, that, when any morbid action is set up in the tongue, many things contribute to maintain it. "The extreme mobility of that organ; the almost continual use of it in eating, drinking, and speaking; the contact of the teeth, which are often irregular and decayed; are quite sufficient to interrupt any efforts to restore a healthy action. It often happens, too, that the part is so very tender, that the patient cannot bear to cleanse the mouth and teeth, which soon become incrusted; and, from this source alone, the complaint will be greatly aggravated, and the discharge rendered fetid and irritating."—(*Med. Chir. Trans. vol.* 12, *p.* 283.) The matter with which the teeth become incrusted in these cases, is composed of phosphate of lime and mucus; and in the case recorded by Paletta, to which I shall presently refer, the quantity of it was very considerable.

Carious teeth, with points and inequalities, producing continual irritation, are the most frequent cause of ulcerations of the tongue. The sores thus arising often resist every kind of remedy, and ignorance of the cause sometimes leads the practitioner to consider them as irremediable; whereas, a cure may easily be effected by extracting the carious tooth, or simply filing off its sharp irregularities, as was anciently directed by Celsus.

The glandular papillæ, situated on the dorsum of the tongue, have a narrow base, and a broad termination or head, like a mushroom. They are capable of becoming considerably enlarged, so as to form preternatural tumours, which may be mistaken for cancerous excrescences.

A young man, eighteen years of age, had on the middle of his tongue a circumscribed tumour about as large as a middle-sized nutmeg. Louis, who was consulted, perceived that the swelling was only of a fungous nature, and he tied its base with a ligature, with the noose of which he contracted the diameter of the pedicle, while with the ends he kept down the tongue. Then, with one stroke of a pair of curved scissors he cut off the tubercle. Caustic was afterward applied to the base of the tumour, and the patient was perfectly well in five or six days.—(*Sur les Maladies de la Langue, in Mém. de l'Acad. de Chir. t.* 5.) Similar tubercles are mentioned by Morgagni.

A peculiar disease of the tongue was met with in a boy by Mr. Earle. Clusters of very minute semitransparent vesicles pervaded the whole thickness of the tongue, occupying nearly one-half, and projecting considerably both above and below that organ. The slightest injury caused them to bleed profusely, and, in some places, the clusters were separated by deep clefts, which discharged a fetid, irritating sanies. This disease, which had resisted various plans of treatment, both local and constitutional, gradually yielded to perfect quiet, cleanliness, large doses of hyoscyamus, which were increased to 3j. of the extract daily."—(*Med. Chir. Trans. vol.* 12, *p.* 285.)

The same medicine, he says, he has employed with most unequivocal good effect in many cases of ragged, irritable ulcers of the tongue.

The tongue is occasionally affected with a true cancerous disease: one of the most afflicting cases indeed which can possibly happen, as may be conceived, when it is known that, in the advanced stage of the disease, the patient can hardly take his food, which must be conveyed over the tongue by some means or another, before it can be swallowed, while he is obliged to write whatever he wishes to say.—(See *Home's Pract. Obs. on Cancer, p.* 112.) Cancer of the tongue seems to differ from other carcinomatous affections in frequently occurring in youngish subjects. In the course of the disease, the glands behind the jaw and in the neck are sometimes affected. Louis saw a lady, who had an ulcerated cancerous tubercle on the left edge of the

tongue. The little swelling was circumscribed; its size did not exceed that of a filbert; the pains were lancinating; the sore had penetrated deeply; and its tuberculated edges were affected with a scirrhous hardness. Extirpation of the disease seemed to present the only chance of cure; but the patient refused to accede to any thing but palliative plans, and she died in the course of a few months.

One of the best descriptions of cancer of the tongue, is that lately published by Mr. Travers. The disease, he says, "is not a smooth and firm rounded tubercle, such as is often met with in this organ, but an irregular rugged knob in its first stage, generally situated in the anterior third, and midway between the raphé and one edge. It sometimes, but seldom, extends across the middle line, although it often extends alongside of it. The hardness is unyielding, inelastic, and the mucous surface puckered and rigid. It also gives to the finger and thumb of the surgeon the sensation of solidity, or of its penetrating the entire muscular substance, being perceived equally on either surface. Sharp shoots of pain are felt through the side of the affected organ, towards the angle of the jaw and ear. The disease tends to run backwards towards the base or posterior edge. It sometimes acquires great bulk before ulceration takes place, so as to project the tongue from the mouth. In this state a female patient of mine was seen some time ago in St. Thomas's Hospital, in whom the permanent projection of the diseased organ, beyond the widely-distended lips, was from three to four inches. Life was sustained for a time by nutritive injections. The ulceration often extends from the edge of the tongue to the membrane of the mouth and gums, when the elevated and distended membrane at length gives way, and ulceration is rapid. The surface of the ulcer is very uneven, clean and bright granulations appearing in parts, and in others deep and sloughy hollows. The darting pain is very acute, but only occasional. There is a dull aching always present, and as constant a spitting as in deep salivation. The irritation is such as soon impairs the powers of life. It happens to strong and hitherto healthy persons, for the most part males from the age of forty onwards. There is generally an evening paroxysm of pain; and the nights are much disturbed by the secretion accumulating in the throat, and exciting cough. Often the patient is roused by a painful compression of the tongue falling between the jaws. The leaden hue of the countenance, the loss of flesh, and difficulty of taking food, although symptoms of the advanced stage of the disease, are observed long before the appetite or muscular powers fail in proportion. Frequent moisture with mild fluids, as tepid milk and water, or confectioners' whey, is grateful to the patient. Towards the fatal termination of the disease, occasional profuse hemorrhages take place at shortening intervals, and alarm and weaken the patient, who ultimately dies tabid and exhausted, generally with symptoms of more extensive disease of the mucous membrane in other parts."—(*Travers, in Med. Chir. Trans. vol.* 15, *p.* 245.)

Forestus makes mention of four women who were attacked with cancer of their tongues, and died from the ravages of the disease and hemorrhage. In the writings of Hildanus, there is a description of the origin and progress of a cancerous tubercle on a young man's tongue, whose breath was intolerably fetid, and who died in the most excruciating pain. The same author informs us of another case, exhibiting the good effects of sedative remedies in palliating a cancerous ulcer of the tongue, and the fatal consequences of an opposite line of conduct.

It is much easier to cut off a portion of the tongue, through all its diameter, than to remove a cancerous ulceration situated at one of its edges.

In both cases there is a good deal of difficulty in fixing the part. For this purpose, Louis recommended the employment of forceps, with blades terminating in hook-like extremities. With this instrument, the part of the tongue about to be amputated can be kept from slipping away.

When any part of the tongue is to be amputated, authors very properly recommend the chief vessels to be tied if possible; but when this cannot be accomplished, they advise the employment of astringent gargles, such as a strong solution of alum, distilled vinegar, or diluted sulphuric acid. When these methods fail, the continental surgeons recommend the actual cautery as the only resource. When only a piece of the tongue is cut out, in the shape of the letter V, the best mode of stopping the bleeding is to bring the sides of the incision together with a suture; by which means, the deformity will also be lessened, and the union expedited, as is exemplified in a case recorded by Langenbeck.—(*Neue Bibl. b.* 2, *p.* 489.) Rather than suffer a patient to die of hemorrhage, if the cautery and other means fail, the lingual artery should be taken up where it passes over the cornu of the os hyoides. Diseased portions of the tongue admit of removal with the ligature.—(*La Motte, Chirurgie, obs.* 208; *Godart, in Journ. de Méd. t.* 13, *p.* 66; *Sir E. Home, Pract. Obs. on Cancer, p.* 207; *Inglis, in Edin. Med. and Surgical Journ.* 1803, *No.* 1, *p.* 34.) Sir E. Home generally passed a double ligature through the centre of the tongue behind the diseased portion, and then tied the threads tightly over each half of the organ, so as to make all the part in front of the constriction slough away.

Mr. Travers is of opinion, that cancer of the tongue only admits of palliative treatment. He has seen but one case in which the ligature or knife had been employed, and in which he did not witness or hear of a recurrence of the disease before a twelvemonth had elapsed. Excision he sets down as hardly safe, when practicable through the sound parts. The actual cautery and the lunar caustic, he says, decidedly aggravate the malady. All stimulant applications, myrrh, alum, zinc, copper, and even borax, he has found to increase the pain and mischief. The carbonate of iron, and alkaline carbonates, according to his experience, are useless. A wash made of two oz. of lime-water, and half a drachm of calomel, suspended in it by means of mucilage, he deems the best application. Opium, locally applied, he says, rarely has an anodyne effect; and he represents the disease as not being permanently influenced either by mercury, steel, arsenic, iodine, prussic acid, bark, or any other medicine. —(See *Med. Chir. Trans. vol.* 15, *p.* 247.)

However, very malignant ulcers on the tongue have sometimes been cured without the removal of the part. Sores of this description are reported to have yielded to the repeated application of leeches under the tongue, after a vast number of other remedies had been tried in vain. In the *Encyclopédie Méthodique, art. Langue*, there is an account of a very alarming affection of the tongue (reputed to be cancerous, though this may be doubted), which got completely well under a very simple plan of treatment. A woman, thirty-five years of age, subject to cutaneous diseases and ill-conditioned ulcers, complained, for seven or eight months, of little swellings, accompanied with heat and pain, which made their appearance on the edge and towards the apex of the tongue. At length, the part affected began to swell, grow hard, and cause lancinating pains. Its surface became irregular and rough; and all the side of the tongue was considerably swelled. The patient could not put her tongue out of her mouth, nor swallow any thing except liquids; and her breath was intolerably fetid. Various sedative remedies had been employed without success. Cicuta had been used as a topical application; it had been exhibited internally in large doses; the patient had taken, for a long while, the oxymuriate of mercury; but nothing proved of any avail. At length, the patient was so tired of trying the effect of medicines and applications, that she gave them up entirely; and contented herself with trying the experiment of keeping some honey continually in her mouth. As this method seemed to give her some ease, she was prevailed upon to persist in it, and in this way the pains were gradually appeased; the swelling was diminished, and at the end of two or three months she was quite well, except that an indurated cicatrix remained on the part affected, and considerably obstructed the extension of the tongue on that side.

On this case, however, it might be remarked, that the retardation of the cure seems also ascribable to the injury of the health produced by the hemlock, mercury, &c.; and that the amendment, following their discontinuance, might rather have arisen from the consequent improvement of the patient's health than from any effect of the honey.

Some inveterate diseases of the tongue may be cured by hemlock. In the work last cited is mentioned

an instance of a very unhealthy-looking ulcer near the apex of the tongue, attended with a considerable thickening of the part, and of some duration, which was cured by giving large doses of cicuta. But of all the medicines which have the greatest reputation for their beneficial effects upon malignant ulcers of the lip and tongue, none perhaps is deserving of so much confidence as arsenic.—(See *C. Lane's case of ill-conditioned Ulcer of the Tongue, successfully treated by Arsenic; Med. Chir. Trans. vol.* 8, *p.* 201.) Mr. Earle's report of the favourable effects of hyoscyamus, I have already noticed: he speaks also in praise of the pulp of carrots retained on the ulcer, and frequently changed.—(*Op. cit. vol.* 12, *p.* 286.)

However, notwithstanding many facts of this kind on record, medicines should not be tried too long, that is to say, so as to let the disease attain a condition in which it will no longer admit of being cut away. When the disease makes progress, the knife should be employed before it is too late.

The whole of the tongue sometimes inflames, and becomes considerably enlarged, either spontaneously and without any apparent cause, or in consequence of some other disease; or else from some particular irritation, such as that of mercury or some poisonous substance. Siegel, who was at Paris about the middle of the 17th century, saw a patient in a salivation, whose tongue became so enormously enlarged that the mouth could not contain it. Pimprenelle, an eminent surgeon of that time, was sent for, and, finding that all trials to relieve the affection were in vain, amputated one-half of the tongue with the view of preventing its mortification. After the wound had healed, it is said the patient could articulate very well. Louis, from whom this fact is quoted, justly remarks, that the measure resorted to by Pimprenelle was an exceedingly violent one; for he has often seen urgent symptoms occasioned, during a salivation, by a rapid and enormous swelling of the tongue, very quickly yield to bleedings, purgative clysters, change of air, and leaving off mercury. Two or three facts confirming this statement have fallen under my own notice.

Trincavellius mentions two women who had considerable enlargements of their tongues. One of these patients, who was young, had been rubbed with mercurial ointment on her head; and in the other, who was about fifty years old, the complaint arose from the small-pox. The excessive swelling of the tongue, in both these instances, terminated in resolution. Another case of ulceration, enlargement, and protrusion of the tongue is recorded by Paletta, who recommended the reduction of the part into the mouth, keeping the jaw closed with a bandage, and the frequent use of vinegar and alum gargles. The result is not stated.—(See *Journ. of Foreign Med. No.* 19, *p.* 457.)

When the urgency is such, that an immediate diminution of the swelling becomes necessary for the relief of the symptoms, the plan of making one or two deep incisions along the tongue is strongly recommended. See the cases inserted by De la Malle, in the 5th vol. 4to. of the *Mém. de l'Acad. de Chirurgie*, and some others, related by Louis in the paper above cited.

A man, recovering from a bad fever, was suddenly attacked with a pain in his tongue, followed by a swelling equally large and rapid in its formation. In less than five hours the part became thrice as large as it is in its natural state; and in this space of time De la Malle, who had been consulted, bled the patient successively in his arm, neck, and foot. The man felt very acute pain, his skin was excessively hot, his face was swelled, his pulse was hard and contracted, and his look wild. He could hardly breathe: the tongue filled all the cavity of the mouth, and protruded between the lips. In this very urgent case, the mouth was kept a little more open than the swelling of the tongue actually caused it to be, and three parallel incisions were made along this organ; one along its middle, and the other two between the one in the centre and the edges of the part affected. The cuts extended through two-thirds of the preternatural swelling, and had all the good effect which could possibly be desired. There was a great deal of hemorrhage, and the enlargement of the tongue subsided so much, that an hour after the operation the patient was able to speak. The next day, the incisions had the appearance of being only superficial scarifications, and the tongue was in its natural state. In short, the incisions healed in a few days, with the use of a simple gargle.

De la Malle quotes several other cases, all of which exhibit the success which he met with from this practice in other similar cases. He quotes also the testimony of authors antecedent to him, who have recommended the method; and, in particular, he cites Job à Meckren, who adopted this practice in a case where the tongue, together with the tonsils and palate, became spontaneously affected with a sudden and dangerous degree of swelling. This treatment is found to answer by modern practitioners.—(See *Journ. Universel, &c. June*, 1823.)

From the preceding observations, it may be concluded, that making incisions in the tongue would have saved numerous patients, who have been suffocated in consequence of enormous enlargements of this organ. In the small-pox, the tongue sometimes becomes immensely swelled; and it is more than probable, that, in many instances, the employment of the above method would have afforded great relief to patients whom the disease has been known to have entirely bereaved of the power of swallowing. It is a curious fact, that after the loss of very considerable portions, or even what may be called the whole tongue, patients often recover the power of speech, mastication, and deglutition.—(*Louis, in Mém. de l'Acad. de Chir. t.* 5; also, *J. Rowland, Aglossostomographie, ou Déscription d'une Bouche sans Langue, laquelle parle, et fait naturellement toutes ses autres Fonctions.* 12*mo. Saumur*, 1630. *Louis sur les Maladies de la Langue, Mémoires de l'Acad. de Chir. t.* 5: also, *the Memoir of De la Malle in the same volume. Encyclopédie Méthodique, partie Chir. art. Langue. Sir Everard Home's Pract. Obs. on Cancer*, 8*vo. Lond.* 1805. *Langenbeck, Neue Bibl. b.* 2, *p.* 487, 8*vo. Hanover*, 1820. *C. Lane and H. Earle, in Med. Chir. Trans. vols.* 8 *and* 12. *B. Travers, op. cit. vol.* 15.)

TONSILS. The tonsils, like all other parts at the back of the mouth, are subject to different kinds of swelling which vary as much in their nature as their consequences. Some are rapid in their progress, and these are frequently observed to affect persons of what is termed a sanguineous temperament. They are also prone to attack young people, and such as labour hard, and they have all the essential characters of inflammation.

Other swellings of the tonsils are slower in their progress, occur in damp cold weather, and in indolent and what the old physicians used to call phlegmatic constitutions.

Lastly, another kind of enlargement of the tonsils, which is usually contagious, readily falls into a sloughing, gangrenous state, sometimes extends to the neighbouring parts, and too often proves fatal. Hence, the various species of angina have been named by some writers inflammatory, catarrhal, and gangrenous. The first two kinds frequently terminate in resolution; but sometimes the affected tonsils afterward assume a scirrhous hardness, and obstruct respiration and deglutition, so that it becomes indispensably necessary either to extirpate them with the ligature or knife.

The cutting away of enlarged tonsils was performed by the ancients in different ways. Sometimes, with their fingers, they tore the membrane covering the tonsil, and then pulled this part out of the situation which it occupies between the pillars of the velum pendulum palati. In other instances, in which they experienced too much resistance, they seized the diseased tonsil with a kind of hook, and then cut it away with a bistoury, which Paulus Ægineta informs us, was concave on the side towards the tongue.

The moderns, who for a long while were timid in the employment of both these methods, adopted plans of a more cruel description. The actual cautery was proposed, and some partial success which followed its use at once established its reputation. Caustics were afterward employed instead of actual fire; but the inconvenience of not being able to limit their action, and the hazard of their falling down the œsophagus, soon caused them to be relinquished by all rational practitioners. Then the operation of cutting away the tonsils was revived; and it was performed, sometimes in the manner of the old surgeons, sometimes with various kinds of curved scissors or knives. Instead of the simple tenaculum, used by the ancients, a sort of double one came into fashion.

Bichat describes the following as once the common plan: the surgeon is to open the mouth very wide, and depress the tongue with any flat instrument, which is to be held by an assistant. The operator is then to take hold of the diseased tonsil with a tenaculum; and with a common scalpel, having the back half of its blade covered with rag, he now removes as much of the tonsil as ought to be taken away. In common cases, it is deemed sufficient to cut on a level with the pillars of the velum pendulum palati. Any other portion, needing removal, should next be taken away. The operation being finished, the patient is frequently to wash his mouth with proper gargles.

The preceding method was long adopted by Desault. However, one objection is urged against it, viz. that when the end of the knife is conveyed far into the mouth it may do mischief, not (as has been alleged) to the internal carotid artery, the backward situation of which completely keeps it out of all danger of being wounded, but to the membranous covering of the palate in a place not corresponding to the tonsils. Desault thought this objection was the more forcible, as when the hook is introduced into the tonsil, the danger of the above mischief is considerably increased by a general spasm, which seems to affect every part of the mouth. Hence, this eminent surgeon used to employ, for the removal of diseased tonsils, an instrument which was first invented for dividing cysts of the bladder. It consisted of a sharp-edged blade, which was included in a silver sheath. The latter had at its extremity a kind of notch, in which the gland about to be extirpated was received. The rest of the instruments were similar to those commonly used. Desault proceeded as follows:

1. The patient being seated on a high chair, with his head supported on an assistant's breast, he is to open his mouth very wide, and the lower jaw is to be kept thus depressed by some solid body placed between the teeth, and held there by an assistant.

2. The tongue is to be kept down with a broad spatula.

3. The surgeon is next to take hold of the tonsil with a double hook, with which he is to raise and draw it a little towards him. He is then to take the above cystotome and put the tonsil in the notch, on a level with the place where the incision is intended to be made.

4. When the portion which is to be cut off is engaged in the notch, the operator is to draw the part towards him so as to stretch it, and press the instrument against it from below upwards. The blade being next pushed across the notch, the necessary section is accomplished. When the division is not complete, which is particularly liable to happen when the diseased gland is of considerable magnitude, the blade is to be drawn back, and the section completed by applying the instrument to the wound which it has already made. Sometimes even a third application may possibly become requisite.

5. The patient is to be directed to wash his mouth. Bichat states, that this plan of operating, adopted by Desault, is as simple and easy as the method above related, with the advantage of being safer. Such is the construction of the blade of the instrument, that when it slides across the notch it presses against, and steadily fixes, the parts which are to be divided, an advantage which neither the knife nor scissors have, under the action of which the parts are quite moveable. Hence, there is difficulty in cutting them. When the introduction of the instrument from above downwards is difficult, it is better to withdraw it; and after turning the notch in the opposite direction, pass it from below upwards. In general, however, the first of these methods is preferable, because the gland, when half cut through, cannot now fall back and obstruct the rima glottidis, so as to bring on danger of a sudden suffocation; a circumstance which Wiseman and Moscati saw happen. With the view of preventing this occurrence, Louis recommended the common scalpel to be used, with its edge directed upwards, as has been advised for the above instrument; which latter contrivance, however, being, according to Bichat's account, more easy and safe, merits the preference. Besides the advantage of fixing the soft parts which are to be cut, it has that of not confusing them, like most other instruments of this nature, as, for instance, scissors; and the oblique disposition of its blade enables it to divide parts in the manner of a saw.

This invention, as Bichat allows, is certainly increasing the number of surgical instruments; a thing which all the best modern surgeons endeavour to avoid. But it is to be recollected, that this instrument is not exclusively applicable to any particular operation. It may be employed for cutting away the tonsils and uvula; dividing membranous fræna in the rectum, vagina, and bladder; amputating fungous excrescences, polypi of the nose (if this mode of extirpating them were preferred), and various tumours in general, which are deeply situated in different cavities of the body, where instruments introduced unguardedly might injure parts which should be avoided, or where the base of the tumour should be steadily fixed, when its division is to be accomplished. The latter object cannot safely be effected by scissors. When the base of the tumour is too large to be received in the notch, one part is first to be divided, and then another, till its whole thickness is cut through.

In England, when a diseased tonsil is to be cut away, surgeons generally prefer a common scalpel.

As a general practice, I consider that the excision of an enlarged tonsil is a better practice than the extirpation of it with a ligature, which also sometimes answers very well, and, perhaps, in children and timid patients, may merit the preference. The chief objections to the ligature are, that its operation is rather tedious, sometimes productive of a great deal of irritation, and on the whole at least as painful as the knife.

Moscati having once adopted this plan, very severe pain and inflammation ensued: the difficulty of swallowing and breathing compelled him to amputate the tumour at the place where the ligature was applied, and all the bad symptoms immediately ceased. Besides, when the ligature is used, there is no oozing of blood from the vessels, a circumstance which tends so much to diminish the inflammation. The base of the swelling is also sometimes broader than its upper part, and does not admit of being properly surrounded with a ligature. And when it has a narrow base, it can then be so easily removed with a scalpel, or with Desault's instrument, and with so little pain, that one of the last modes is generally preferable.

The ligature, however, has had its advocates. Heister recommends it in certain cases; Sharp praises it; and others approve its use; while the plans of employing it have been as various as the inventive genius of the different partisans of the practice. Some make use of Levret's double cannula, which is furnished with a silver wire noose, in which the tumour is to be engaged. By twisting the instrument, the diseased part becomes constricted. Some, after putting the noose of a ligature over a kind of tenaculum, take hold of the tonsil, push the ligature over the enlarged gland, which they tie, without having any means of increasing the constriction afterward. Others employ Belloque's instrument for putting the ligature over the tonsil. Sir A. Cooper, who prefers the ligature to excision, gives to an eye-probe the requisite curve, and then passes the ligature with it behind the enlarged tonsil. The probe being then removed, the knot is made with tonsil-irons, if the fingers are not long enough for the purpose.

Desault employed an instrument which the French call *un serre-nœud*, which is in fact nothing more than a long, narrow, round piece of silver, terminating at one end in a little ring or hole, and at the other in a kind of groove or notch.

1. The patient was seated on a high chair with his head held back on an assistant's breast; his mouth was opened very wide, his tongue depressed, and the diseased tonsil taken hold of with a double hook.

2. The surgeon took the *serre-nœud*, in which a ligature had been passed, so as to form a noose. The noose was put over the handle of the hook, which was committed to the charge of an assistant, and the noose then pushed over the tonsil, so as to embrace it completely.

3. The surgeon now drew the ligature strongly towards him, and pushed forward the *serre-nœud*, so as to produce the requisite constriction of the tumour. In general the ligature was not made very tight the first day.

4. When the necessary constriction had been made, the double hook was withdrawn, and the ligature twisted round the notch at the outward end of the instrument.

5. The next day the gland became unusually large, in consequence of the impediment to the return of the venous blood. The ligature was unfastened from the notched end of the instrument, and drawn more out, so as to increase the constriction, after which it was again twisted round the notch. This plan was followed up till the tumour was detached, which usually happened on the fourth or fifth day.

The late Mr. Chevalier described a particular mode of passing and securing the ligature. He passed a flat spear-pointed hook behind the diseased tonsil, and its point was then pushed forwards so as to perforate it through the middle of its base. The needle was then withdrawn, an eye-probe very much curved, and armed with a long double ligature, was then readily passed through the perforation and brought out at the mouth, the ligature divided, and one portion tied round the upper half of the tonsil and the other round the lower. "A single knot being first made upon one end of the thread, the end so knotted is to be brought forwards upon the other, and to make a single noose upon itself including the other, and to be drawn tight upon it close to the first knot. The free end of the thread is then to be passed" through a ring at the end of an instrument for the purpose, and "being then held firm, and the ring pushed forwards upon the knot, the loop now formed may be readily tightened, so as completely to strangulate the diseased part; and in the same manner it may be tightened from day to day, till the part is entirely detached."—(See *Med. Chir. Trans. vol.* 3, *p.* 80, *&c.*) The subject is more intelligible with the plate.

Sometimes, in angina, the tonsils are suddenly attacked with such a degree of swelling, that respiration is dangerously obstructed. This case is analogous to the occasional enormous inflammatory swelling of the tongue, and if it resist venesection and leeches, the most prompt mode of relief is that of making several deep scarifications with a knife in the part. Many examples confirming the good effects of this practice have been seen by Langenbeck.—(See *Neue Bibl. b.* 2, *p.* 492, *&c.*)

[In the Medical and Physical Journal of Philadelphia, No. 1, Dr. Physick has given a description of a method of removing enlarged tonsils by a double cannula and iron wire. This method has been so long before the profession, that it is unnecessary to describe it here, especially as removing them by the knife is now generally preferred. The same distinguished surgeon has constructed an instrument for excision of the tonsils, which he now prefers to the ligature. It is composed of two steel pieces, attached to one end of each is a steel ring; between the two is a lancet-shaped blade moveable on two screws which connect the pieces. The tonsil is fixed in the rings, and the blade thrust forwards by pressing with the thumb on a button at the extremity of the handle, when it will be divided. In the American Medical Recorder for 1828, Dr. Matthews, of Philadelphia, has described another instrument for the same purpose. Professor Stevens, of New-York, has described in the N. Y. Med. and Phys. Journal for 1828, an instrument for the removal of the tonsils by a wire ligature, which is greatly preferable to that of Dr. Physick, when this method is adopted instead of the knife. Dr. Cox, of New-York, has also proposed a method of excising the tonsils, which seems to be superior to either of the numerous processes which have been published by way of improvements in this operation. A description of his instrument may be found in the N. Y. Med. and Phys. Journal for 1829.—*Reese.*]

TOPHUS. A swelling which particularly affects a bone or the periosteum. See *Node.*

TORTICOLLIS. (From *torqueo*, to twist; and *collum*, the neck.) The wry-neck. See *Wry-neck.*

TOURNIQUET. (*French*, from *tourner*, to turn.) An instrument for stopping the flow of blood into a limb, until some requisite operation has been performed, or a more permanent plan of checking hemorrhage has been put in practice.

The old surgeons used to surround the limb with a band, with which they made such a degree of constriction, that the circulation was quite stopped. They also believed that the pressure of the band was advantageous in benumbing the limb and moderating the pain of operations.

The violent pain and contusion, however, which such a tourniquet occasioned, being frequently followed by abscesses, and even by mortification, surgeons found it necessary to devise some other method for checking hemorrhage. The application of the circular band was first improved, so that it caused less pain and less mischief to the skin. The limb was surrounded with a very thick compress, over which the band was placed. Two small sticks were next put under the band; one on the inside, the other on the outside of the limb; and they were twisted till the band was rendered sufficiently tight. It is in this manner, says Dionis, in his *Traité d'Opérations*, that carriers tighten the cords which fasten the bales of goods in their carts. A French surgeon named Morel, is said to have made this first improvement in the application of tourniquets.

J. L. Petit, in 1718, presented to the Academy of Sciences a tourniquet of his own invention, which was much more perfect, though certainly very complex, when compared with that which is used by the best modern practitioners; but still it is the original of the latter, and both are constructed on the same principles. All the pieces of modern tourniquets are connected together; and, instead of two pieces of wood used by Petit, there is a brass bridge which is capable of being elevated or depressed, by means of a screw made of the same metal. Over this bridge a very strong band proceeds, and by passing under two little rollers at each end of the bridge, it always remains connected with the instrument. A convex firm pad is sewed to the band and put immediately over the artery where the instrument is applied. There are no cushions for the opposite side of the limb under the screw; but a thick piece of leather, through which the band proceeds in two places, is always situated under the lower surface of the brass, and serves to prevent any bad effects of its pressure. It is usual also for the surgeon to fold some rag and to put it in this situation, at the time of applying the instrument.—(See *Hemorrhage.*)

The following are the advantages of the modern tourniquet, formed on the principles of that first invented by Petit: 1. It compresses the lateral parts of the limb less than the tourniquet previously in use. 2. It requires the aid of no assistant either to hold, tighten, or loosen it. 3. The operator is able of himself to stop the flow of blood in the artery, by means of the screw. 4. When there is any danger of hemorrhage after an operation, it may be left on the limb, and in case of bleeding, the patient, if no one be at hand, can tighten the instrument himself as much as is necessary. 5. Its constriction produces less danger of mortification, because it does not altogether stop the flow of blood through the collateral arteries. The interruption of the circulation in parts of the body by the tourniquet, has been tried as a means of relieving diseases.—(See *G. Kellie, Obs. on the Medical Effects of Compression by the Tourniquet*, 8vo. *Edinb.* 1797.)

[Dr. Moore, of Massachusetts, has described, in the New-England Journal, a tourniquet of his invention, which is very generally adopted by those surgeons in this country who have not laid aside the use of this instrument in their amputations. Many of the most distinguished American surgeons dispense with the tourniquet altogether, preferring to rely upon compression made on the principal artery of the limb by a competent assistant. It is certain that much less hemorrhage attends an amputation than when any modification of this instrument is used, and in very many cases the success of the operation is overthrown by the loss of blood.

That the use of the tourniquet does increase the hemorrhage will be apparent to any who ever operate without one, and although the bleeding is chiefly from the portion of the limb amputated, yet the debility induced is not the less on this account. On the first application of this instrument to the thigh, for example, the compression is made on the superficial veins, the return of the blood prevented, and the morbid state of the limb often favours the consequent engorgement. As the instrument is screwed, the turgescence of the limb below the point at which the compression is made continues to increase until the circulation is stopped. No sooner is the incision made, than a hemorrhage of very considerable extent takes place, and the assistant is directed to tighten the instrument, which fails to

suppress it, because the blood flows from the vessels of the limb below the incision, thus unnaturally distended. Every operative surgeon must have suffered inconvenience, and often anxiety from this source, and yet few have blamed the tourniquet, which is the true cause of the mischief.

I have operated myself, and witnessed the amputation of the thigh by Dr. Bushe and others, where the femoral artery was suddenly compressed by the fingers of an assistant, and the hemorrhage was always very inconsiderable, often not more than half a pint during the whole operation. I believe the time is not very remote when this instrument will be every where abandoned, except where the surgeon is obliged to operate without an assistant, and in such cases the inconvenience will have to be submitted to of course.—*Reese.*]

TRACHEA, Wounds of. See *Throat.*

TRACHEOTOMY. (From τραχεῖα, the windpipe, and τέμνω, to cut.) The operation of cutting an opening into the windpipe for various surgical purposes. See *Bronchotomy.*

TREPAN. (From τρυπάω, to perforate.) *Trepanum; Terebellum; Modiolus.* A circular saw, by means of which the skull is perforated in the operation called *trepanning*, or a circular portion of any bone may be sawed out. It bears a considerable resemblance to the well-known instrument named a wimble, and is worked in the same manner. Formerly the saw was sometimes made of a conical shape (see *Abaptiston*); but this construction rendered the action of the instrument difficult. In this country the trepan is now superseded by the instrument, called a *trephine*, which has a different handle, and is not worked in the same way. On the continent, however, the trepan still has the preference.

TREPHINE. The instrument now commonly preferred for perforating the cranium, for purposes which I shall presently explain. It consists of a simple cylindrical saw, with a handle placed transversely like that of a gimlet; and, from the centre of the circle, which the teeth of the saw describe, a sharp little perforator projects, named the centre-pin. The upper part of the centre-pin is made to screw in a corresponding hole at the inside of the top of the saw, and is capable of being taken out or put in, at the surgeon's option, by means of a little key for the purpose. Its use is to fix the trephine when it is first applied, that is, before the teeth of the instrument have made a sufficient circular groove, in which they can steadily work. When this has been accomplished, the centre-pin must always be removed; because now it is not only unnecessary, but, if left, would retard the progress of the operation, and inevitably wound the dura mater and brain, when the teeth of the saw had cut to a certain depth through the cranium. My trephines have their centre-pins contrived to slide up or down, and to be fixed in either position by turning a little screw. This method seems to me both ingenious and convenient.

The cylindrical part of the trephine is often termed the *crown* of the instrument. The surgeon should have at least two or three cylindrical saws of various sizes; for it is always a commendable rule never to saw away any more of the cranium than is absolutely requisite for the accomplishment of some rational object. There is no occasion, however, for having more than one handle, which may be made to screw on any of the saws.

Trephines are also occasionally applied to other bones, besides those of the cranium. In the articles *Antrum*, *Caries*, *Exostosis*, *Fractures of the Sternum*, *Necrosis*, *Spina Ventosa*, other cases are mentioned in which the employment of these instruments sometimes becomes proper.

It is not always desirable to remove a complete circular portion of the cranium, the taking away of a piece of smaller size, and of a different shape, being frequently much more advantageous. Some surgeons, who object to removing any unnecessary quantity of the cranium, occasionally employ a trephine, terminating only in a semicircular, instead of a circular saw, by which means they can often cut across the base of a depressed portion of the skull, and take it away, without any occasion for removing also a circular piece of bone. An instrument of the latter kind may certainly be sometimes useful.

The saws, however, which Mr. Hey has described, should constantly be kept in every case of trephining instruments. This practical writer remarks, that "the purposes for which any portion of the cranium is removed are, to enable the surgeon to extract broken fragments of bone, to elevate what is depressed, and to afford a proper issue to blood or matter that is or may be confined, &c.

"When a broken fragment of bone is driven beneath the sound contiguous part of the cranium, it frequently happens that the extraction cannot be executed without removing some of the unbroken part, under which the fragment is depressed. This might generally be effected with very little loss of sound bone, if a narrow portion of that which lies over the broken fragment could be removed. But such a portion cannot be removed with the trephine. This instrument can only saw out a circular piece. And, as in executing this, the central pin of the saw must be placed upon the uninjured bone, it is evident that a portion of the sound bone, greater than half the area of the trephine, must be removed at every operation. When the broken and depressed fragment is large, a repeated application of the trephine is often necessary, and a great destruction of sound bone must be the consequence.

"When the injury consists merely of a fissure with depression, a small enlargement of the fissure would enable the surgeon to introduce the point of the elevator, so as to raise the depressed bone. But a small enlargement of the fissure cannot be made with the trephine. When it is necessary to apply the elevator to different parts of the depressed bone, a great deal of the sound cranium must be removed, where a very narrow aperture would have been sufficient.

"The same reasoning will apply to the case of openings made for the purpose of giving a discharge to extravasated blood or matter.

"If a saw could be contrived which might be worked with safety in a straight or gently curvilinear direction, it would be a great acquisition to the practical surgeon. Such a saw I can now with confidence recommend, after a trial of twenty years, during which time I have rarely used the trephine in fractures of the skull. Its use has been adopted by my colleagues at the General Infirmary in Leeds; and will be adopted I hope, by every surgeon who has once made trial of it." Mr. Hey next informs us, that the instrument was first shown to him by Dr. Cockell, of Pontefract; but that there is a saw formed on the same principle in Scultetus's *Armamentarium Chirurgicum.* The saws alluded to are very short ones, fixed at the end of a longish straight handle; their edges are made either straight or semicircular. The latter construction qualifies the instrument for cutting in a curvilinear direction, which is often proper. The edge of the saw should always be made a little thicker than the rest of the blade, by which means it will work in the groove which is cut with more facility.

Saws made on the principle just described are also of infinite use in cutting away diseased portions of other bones, besides the skull, exostoses, &c. In necrosis, when a dead part of a bone is quite wedged in the substance of the surrounding new bony matter, Mr. Hey's saws may often be advantageously employed for cutting away the parts which mechanically prevent the detachment of the dead pieces. The saws invented by Mr. Machell and Professor Graefe are also highly ingenious, and particularly merit attention, when there is very little room for the working of the instrument, and the bone to be cut lies deep. They are wheel-like saws, turned by machinery.

Besides trephines of various sizes, and the saws just now noticed, the surgeon should also take care to have in his case of trephining instruments a little brush for occasionally cleansing away the particles of bone from the teeth of the saw in the progress of the operation; a pair of forceps for extracting the round piece of bone after it has been detached by the saw; a lenticular for removing any inequalities which may present themselves round the sawed edge of the cranium after the circular piece is taken out; a raspatory for the same purpose, and also for scraping the bone in order to see whether it will bleed, which is a circumstance in some cases very important to be attended to (see *Head, Injuries of*); a largish common scalpel for dividing the scalp, &c.; and some elevators for raising depressed pieces of bone.

The common elevator is now generally used by all

the best English surgeons but several others have been proposed, as, for instance, the tripod elevator; and another invented by J. L. Petit, and afterward improved by M. Louis.

Before beginning the description of the operation, I think it highly proper to remind the reader of what has been so forcibly dwelt upon in the article *Head, Injuries of*,—that generally the removal of pressure off the brain, which pressure must also actually occasion dangerous symptoms, can form the only true and vindicable reason for employing the trephine, or sawing away any portion of the skull. There are very few exceptions to this remark: it may, indeed, be now and then proper to saw away the bony edges around some fungous excrescences which grow from the dura mater, and make their way outwards by occasioning an absorption of the part of the skull immediately over them. —(See *Dura Mater.*) It may also be sometimes proper to saw out diseased portions of the skull, though it must be confessed, that in general their separation should be left to time and nature. Loose splinters should always be removed. and, perhaps, if the depressed portion of bone be denuded in a wound of the scalp, a trial to raise it with the elevator will be proper, even though urgent symptoms of pressure may not exist. In such a case, Sir A. Cooper sanctions the application of the trephine (*Lectures, vol.* 1, *p.* 343); but it is contrary to the principle which I conceive ought generally here to be our guide.

It is true that suppuration of the dura mater may follow in such a case; but I do not believe that trephining would tend to prevent it, the right treatment consisting in antiphlogistic measures; and that we should only proceed to remove bone when the symptoms indicate the confinement of matter under it, or injurious effects from the continuance of a depression that in the first instance, perhaps, produced no unfavourable symptoms. On this point, however, I deem it fair to mention, that Mr. Brodie coincides with Sir Astley Cooper, and lays down the following general rule: that if the depression be exposed in consequence of a wound of the scalp, let the surgeon apply the trephine, and elevate the depression; but if there be a depression without a wound of the scalp, in consequence of the accident, let him not make such a wound by an operation.—(See *Med. Chir. Trans. vol.* 14, *p.* 403.)

In the records of surgery innumerable facts may be consulted, where the prudent and judicious employment of the trepan has effected wonderful cures, and been the only thing by which the patients' lives could possibly have been saved. The benefit which the operation brings about is also sometimes so sudden and astonishing, that in no instance does the interposition of the surgical art display itself to greater advantage. The immediate restoration of sight by the depression or extraction of an opaque substance from the eye, is not more beautiful and striking than the instantaneous communication of the intellectual faculties, and of the powers of speech, of feeling, &c., together with voluntary motion, to a person lying in an apparently lifeless state from an injury of the head. The utility of the trepan is occasionally manifested even in this degree. In the valuable essay of Mr. Abernethy on injuries of the head, a case may be seen in which the patient, who had been in a condition almost bereft of animation, rose up and spoke the instant the extravasated blood was removed from the surface of the brain: and among the wounded at the battle of Waterloo, there was a soldier of the 44th regiment, whose case is of equal interest. He had been struck by a musket-ball on the right parietal bone, which was exposed, but had no appearance of being fractured. As, however, the symptoms of compression were urgent, and the patient was in nearly a lifeless state, I conceived it right to apply the trephine to the part on which the violence had acted. I had not sawed long before the external table came away in the hollow of the trephine, leaving the inner table behind, which was not only splintered, but driven at one point more than half an inch into the membranes and substance of the brain. No sooner were the fragments taken out with a pair of forceps, than the man instantly sat up in his bed, looked around, and began to speak with the utmost rationality. It is a most extraordinary fact, that this patient got up and dressed himself the same day, without leave from the medical officers, and never had a bad symptom afterward. Immediately the operation was finished the temporal arteries were opened, and some purgative medicines exhibited.

Mr. Brodie has seen a case in which there was a fracture with distinct depression of the inner table, while there was a simple fissure, which was scarcely perceptible, and that without the smallest depression, of the outer table. He also adverts to the example recorded by Tulpius, in which there were extensive fissures of the inner table, although the outer one remained uninjured; and to another, mentioned by Paré, in which, while the outer table was entire the inner table was broken into splinters, some of which were actually driven into the substance of the brain. In all fractures of the cranium with depression, it is remarked, that the inner table is always broken to a greater extent than the outer one; and the actual depression greater than would appear from the mere inspection of the external fracture. These circumstances are imputed to the greater elasticity of the outer table, and greater brittleness of the inner.—(*Brodie, in Med. Chir. Trans. vol.* 14, *p.* 330.)

In a case of fungus of the dura mater, with diseased bone, mentioned by Schmucker, the trepan was applied eleven times in less than a month, and the operation used to cause so little indisposition, that the patient hardly ever required to go to bed afterward, and on one occasion actually went to market an hour after its performance.—(*Wahrnehmungen, b.* 1, *p.* 456.)

Let not the young surgeon, however, imbibe from a few dazzling examples of success an immoderate solicitude to perform the operation; for it should never be undertaken but in the most pressing circumstances, and when the symptoms unequivocally show that a dangerous degree of pressure on the brain exists. I recollect an unfortunate example, in which the late Mr. Ramsden, of St. Bartholomew's Hospital, ventured to saw out a portion of the frontal bone for a mere long-continued pain in the part: the patient was attacked with inflammation of the dura mater, and perished in three or four days. Two analogous cases of the needless use of the trephine, with similarly tragical results, are also mentioned by Mr. Brodie.—(See *Med. Chir Trans. vol.* 14, *p.* 394.) That the removal of bone creates some risk of a subsequent ulceration and sloughing of the dura mater, and protrusion of the brain, is now a fact universally admitted. We may therefore conclude that the operation is not itself exempt from danger; and it is certain, that it ought never to be resolved on without deep consideration. "*Gravis tamen satis est operatio, ut nunquam, nisi indicationes sufficientes adsint, institui debet.*"—(*Callisen, Syst. Chir. Hodiern. tom.* 1, *p.* 658.)

In cases of injuries of the head, the trepan or trephine is never necessary, except for the purpose of relieving the brain from pressure. Such pressure may be caused by a depressed portion of the cranium, or it may be produced by an extravasation of blood, or the lodgement of matter, between the skull and the dura mater. The chief danger of concussion, when the accident is not directly or soon fatal from the disorganization and mischief done to the brain, depends upon the consequent inflammation of this organ, and therefore cannot be likely to be benefited by the trepan. If the operation become proper in such a case, it is when an abscess has formed under the cranium, and when the confined matter itself creates bad symptoms by its pressure on the brain. This state of things, however, cannot come on till after the inflammation of the brain and its membranes has prevailed a certain time, and it is always accompanied with a detachment of the pericranium and a puffy tumour of the scalp; or, if there be a wound of the latter part immediately over the abscess, the lips of the injury suddenly acquire an unfavourable appearance and lose their vermilion colour. The patient has also had much preceding febrile disorder, pain and tension over the whole head, redness and turgescence of the eyes, and generally more or less delirium. When the matter is forming there are usually rigors, and, as soon as it is formed, the patient falls into a comatose state, and paralytic symptoms show themselves. Here the urgency for the prompt application of the trephine is very great, and the patient's only chance of living is almost essentially connected with the immediate performance of the operation. This important case has been particularly dwelt upon in the writings of Mr. Pott.

In the article *Head, Injuries of*, I have laid down the most remarkable symptoms of concussion and compression of the brain; a subject which every surgeon should study with earnest attention before he ever presumes to employ the trepan. For sometimes these accidents are extremely difficult to be discriminated; sometimes they exist together in the same individual, a complication which is peculiarly embarrassing; and, in every instance, where the symptoms are those of concussion, the operation, so far from being indicated, would be a step of all others the most likely to do harm, by increasing the irritation and inflammation of the brain and its membranes. A fall upon the back or upon the head occasions a direct concussion of the brain; and the shock, not being materially weakened by the intervention of any yielding elastic structure, is the more dangerous. When a person has fallen from a certain height, and pitched on his head, his back, the buttocks, the knees, or even the soles of the feet; when he has been instantly deprived of his senses, and then by degrees recovered them and come to himself again; the fact of his having suffered concussion of the brain is clear and indisputable. Concussion has likewise taken place, though in a slighter degree, when the patient has been only stunned by the fall, and experienced a sensation of sparks. But, a multitude of degrees separate this feebie concussion from that in which the substance of the brain is instantaneously disorganized, so that there is not the possibility of recovery.

The symptoms of concussion of the brain are attended with coma, and the compression of this organ by an extravasation is also accompanied with lethargic heaviness. How then is the surgeon to ascertain whether the comatose disorder arises from one or the other of these affections?

Here, in order to avoid repetitions, I beg leave to refer to the observations already made in the abovementioned article. But there is one criterion of such importance, that it may prevent innumerable fatal mistakes, and, indeed, without the continual recollection of it no man ought to interfere with this dark and abstruse part of surgery. On this account I shall mention it here, notwithstanding it has been already noticed elsewhere. If the patient has been knocked down and stunned directly by the blow, and remain in a state of insensibility, these primary symptoms are ascribable to the concussion. On the contrary, when the coma and loss of sense do not take place till an hour or two after the blow, they are to be imputed to an extravasation.

The shock given to the brain by concussion must, like every other impulse communicated, continue to diminish until it ceases altogether. If, at the very time of the blow, the shock has not been forcible enough to produce alarming symptoms, such symptoms will not afterward come on when their cause is weakened. Hence the reason why compression can be distinguished from concussion of the brain, when there has been an interval of sense between the receipt of the blow and the occurrence of the bad symptoms. But the distinction of the symptoms into primary and consecutive cannot be made when concussion and extravasation exist together.

Having made these few remarks on concussion and compression of the brain, remarks which seemed necessary before I entered into a description of the operation of the trepan, I shall next premise some observations relative to contusions and fractures of the skull, cases on which the most erroneous opinions have been entertained. It is true, that I have in another place (see *Head, Injuries of*,) considered the subject; but it may be better to recapitulate certain points here, because they have such immediate connexion with the application of the trephine.

Contusions of the head not unfrequently occasion a small kind of tumour, which is soft in the centre, but hard and resisting at the circumference, especially when the violence has been considerable. Now the ease with which the centre or seat of the extravasated fluid admits of being depressed, while the circumference remains hard and elevated, is extremely apt to give rise to the belief, that a fracture with depression has happened. The true nature of this accident was first clearly explained by J. L. Petit, and since his time, the proper cautions not to fall into a mistake concerning it have been laid down by the generality of surgical writers.

Often nothing is more obscure, than the diagnosis of fractures of the cranium: their existence indeed can only be made out with certainty when they can be felt or seen. Thus a fracture of the skull, attended with a wound of the scalp and exposure of the bone, shows itself in the form of a fissure more or less wide and extensive, and taking various directions. The accident may also be known by the touch even when the soft parts continue entire, particularly if the fracture is accompanied with splinters, or the edges of the fissure are materially separated. When there are many splinters, entirely detached, a crepitus will likewise serve to explain the nature of the accident; but, unassisted by these symptoms, imparted to him by the sight, the hearing, or the touch, the practitioner cannot at once offer a decided opinion as to whether a fracture exists or not.

In order to procure more positive information, would it be right and judicious to make several incisions and uncover the bone? But here the surgeon would be embarrassed in the very commencement of his proceedings; for how would he be able to judge where the knife should be applied? Why also should he resort to a useless and painful operation, which (to say the best of it) would only render the patient's cure more distant?

The symptoms indicating compression of the brain can alone justify an examination of the fracture. These symptoms also must be urgent and alarming; for when they prevail in a slight degree, bleeding and evacuations promise more benefit than any operation on the skull; and consequently all examination of the part supposed to be broken must be unnecessary.

Even when the cranium has been denuded, so that the sight can convey due information respecting the solution of continuity in the bone, care must be taken not to be deceived by a suture, or by the groove of a vessel. In cases of doubt, a modern surgical author advises us to scrape the outside of the bone; and he tells us, that if after the removal of the external scale the fissure yet appear, and a thread of blood be seen at its outer part, no doubt exists of its being a real fissure. As, however, making this examination can answer no purpose, except with a view to determine the place where the trepan should be applied, I cannot recommend the plan, except where the symptoms are such as to render this information desirable. On the contrary, it appears to me, that all examinations of the bone, made seemingly from mere curiosity, and without any true surgical object, should be deprecated as rash and hurtful.

The danger of fractures of the skull does not depend upon the simple solution of continuity: it bears altogether a relation to the concussion and compression of the brain, with which the injury of the bone may be complicated. The pressure caused by depressed splinters of bone is less alarming, inasmuch as the cause of the compression is easy of removal. The pressure of extravasated fluid is far more serious, in consequence of the difficulty of ascertaining positively its existence and precise situation.

Its seat is sometimes between the skull and the dura mater, which is detached from the bone. More frequently it occurs either between the dura mater and tunica arachnoides, in the substance of the brain, or else in the ventricles. The quantity of extravasated fluid is generally less in those extravasations which are situated between the dura mater and the skull, unless they lie in the course of the middle meningeal artery, when they are frequently very copious. The extravasations which are formed in the substance of the brain itself are not only more considerable, but also, as they mostly depend upon concussion, are more alarming, than effusions on the surface of the dura mater. It is indeed extremely difficult, if not impossible, to ascertain the situation of the extravasated fluid. In such cases, the trepan is likewise of no use; while concussion, when so violent as to produce internal extravasation, is invariably fatal. In extravasations between the dura mater and the skull, which are almost the only cases of the kind to which surgery can administer relief, when the effused fluid lies under a part of the skull accessible to the trepan, the extravasated fluid is generally, except in the instance just now specified, small in quantity. The danger, however, is not the less: ten or twelve drops of fluid are sometimes enough to produce a fatal compression

When the extravasation has happened in the substance of the brain, the compression is far more perilous: in short, it may be said to prove, with very few exceptions, certainly mortal.

The lethargy, the degrees of which increase from mere drowsiness into the most perfect coma; and the paralysis of the opposite side of the body to the seat of the extravasation; are the most common symptoms of this accident. Having explained elsewhere (see *Head, Injuries of,*) some other symptoms, such as stertorous respiration, dilated pupils, &c., which usually indicate pressure on the brain, it is unnecessary here to dwell upon them. The subsequent increase of the coma and paralytic affections, and the gradual augmentation of their intensity, serve to render these symptoms distinguishable from others which are suddenly brought on by concussion. But there are instances, as every man of experience knows, in which concussion ruptures the blood-vessels, and produces an extravasation of blood. In this circumstance, it is obvious that the symptoms of compression are blended with those of concussion. The symptoms proceeding from the latter cause always diminish in proportion to the time which has elapsed from the moment of the injury; while those of compression succeed, and, on the contrary, increase in intensity, in proportion as the quantity of extravasated fluid becomes more considerable. Notwithstanding these distinctions, however, it must be acknowledged, that there are many cases in which the surgeon is obliged to remain in doubt with regard to the particular cause of the symptoms. This indecision is the more embarrassing, because the operation of the trepan is necessary in cases of extravasation, but useless in those of concussion. Even when extravasation is known to exist, the practitioner requires more information; for he ought to know the precise situation of the effused fluid. It is true, indeed, that paralysis of one side of the body generally indicates the pressure to be upon the opposite hemisphere of the brain. But what surgeon would venture to follow the practice advised by Van Swieten, and apply to the suspected side of the head three crowns of the trepan? Possibly, not one of them might fall on the situation of the extravasated fluid. When the skull is broken, the extravasation is almost always on the same side as the fracture. When it is the effect of concussion, or when the breach of continuity in the skull is what is termed a counter-fissure, the effusion is generally on the side of the head most remote from the blow. If the pressure is caused by a detachment of the internal table of the skull, the nature of the case cannot be ascertained before the operation of the trepan has been performed on the part of the skull upon which the violence has acted. When there are two extravasations, one depending upon a fracture, and situated immediately under it, between the dura mater and the skull; the other arising from concussion, and situated at some point directly opposite, either between the dura mater and tunica arachnoides, or within the substance of the brain itself: paralysis may occur on the same side as the fracture; and hence it may be inferred, that the palsy does not always take place on the side opposite to the extravasation. But, says Richerand, an examination of the body quickly proves that the case does not deviate from the common rule. The extravasation produced by concussion being almost invariably more considerable than that caused by a fracture, accounts for the extension of the palsy to the same side of the body. Sometimes the side which is not paralytic is affected with convulsions, the pulse is full and hard, and the respiration stertorous; in short, the symptoms are analogous to those caused by apoplexy.

The following observations and advice fully accord with the doctrines which I have always inculcated in my writings upon this part of surgery, and they also agree with the practice which was so successfully adopted by me in the case of the soldier of the 44th regiment, wounded at the battle of Waterloo, as already mentioned: it is therefore with much pleasure that I quote the authority of Mr. Brodie on a point about which practitioners have been so much perplexed: "Blood (says Mr. Brodie) is seldom poured out in any considerable quantity between the dura mater and the bone, except in consequence of a laceration of the middle meningeal artery, or one of its principal branches; and it is very rare for this accident to occur, except as a consequence of fracture. If, therefore, we find the patient lying in a state of stupor, and on examining the head we discover a fracture with or without depression, extending in the direction of the middle meningeal artery, although the existence of an extravasation on the surface of the dura mater is not thereby reduced to an absolute certainty, it is rendered highly probable, and the surgeon, under these circumstances, would neglect his duty if he omitted to apply the trephine; and where no fracture is discoverable, yet *if there is other evidence of the injury having fallen on that part of the cranium in which the middle meningeal artery is situated, the use of the trephine may be resorted to on speculation, rather than that the patient should be left to die without an attempt being made for his preservation.* I cannot, indeed, adduce any particular experience of my own in favour of what is here recommended; but I conceive, that the instances which have been recorded, in which the middle meningeal artery has been ruptured without any fracture of the bone, and the known fact that there is sometimes a fracture of the inner table of the skull, while there is none of the outer table, sufficiently justify such an experiment in desperate cases." —(*Brodie, in Med. Chir. Trans. vol.* 14, *p.* 385.)

With the foregoing exception, in which, indeed, a ground for suspecting the seat of the effused blood rests upon the knowledge of the exact part on which the violence has operated, the evacuating plan, recommended for the treatment of concussion (see *Head, Injuries of*), is all that can be done when every thing is uncertain relative to the situation of the extravasation. It is all that can be done in those frequent instances where the effusion has taken place in the substance of the brain, so that it cannot possibly be voided. The trepan then is indicated only when there is an extravasation between the dura mater and the bone, the fracture being situated at a part of the skull accessible to instruments, and not at the base. We shall not here dwell upon the doubtful example, where the fluid lies between the dura mater and the arachnoides. I believe that the operation should be limited to a small number of cases, in which not only the existence and situation of the pressure are known, or may be suspected on the ground above explained, but in which the symptoms arising from this cause are urgent and dangerous, and the pressure can be removed by no other means.

Desault in the last years of his practice abandoned the operation of the trepan altogether, its ill success at the Hôtel-Dieu having become notorious. Surgeons of the present day trephine with more caution and discrimination, and sometimes with striking success.

When the case is a simple fissure, the trepan ought to be applied upon the solution of continuity, *if the symptoms indicate a dangerous degree of pressure on the brain.*

When the detached portions of bone are depressed, so as to compress the brain, the operation is still requisite if they cannot be elevated by other means. But Richerand maintains, that a positive indication for trepanning is not frequent, either because it is difficult to judge of the existence and situation of extravasations, or because extravasated fluids readily escape through the interspaces of the fragments, when there is a splintered fracture. Such facility is also increased when one of the portions of broken bone is totally detached, so that it can be removed, leaving an aperture equivalent to what would be produced by the application of the trepan.

When the operation is determined on, the head should be shaved; indeed, this is often done immediately the surgeon is called, in order that he may have a better opportunity of seeing what parts of the scalp have been struck; for it is in such situations that he has most reason to apprehend fractures of the bone, or extravasations beneath it. If, however, the violence has occasioned a large wound or laceration of the scalp, the practitioner, knowing where the force has been applied, is frequently content with having a little of the hair shaved off the parts surrounding the injury All that need be said on this subject is, that it is always better to have enough of the hair taken away, to afford the surgeon an uninterrupted opportunity of examining the scalp freely, and doing whatever may be necessary. The loss of a little hair is of very little consequence, while the concealment of the seat of a depressed

fracture, or extravasation, might lead to fatal consequences.

When the propriety and necessity of trephining are fully indicated, provided the wound or laceration of the scalp should not have exposed a sufficient surface of the bone for the application of the crown of the trephine, an adequate dilatation of such wound ought immediately to be made. If, in the situation of the blow, there should only be a contusion, or a lump, unattended with any wound, a division of this part of the scalp is to be made by carrying the knife quite down to the bone. In those cases in which the swelling occasioned by the violence is considerable, and attended with the sensation of a crepitus; as well as in other instances, in which there is only a contusion, under which a fracture and displaced pieces of bone may be felt; the scalp must be divided in the same manner, only with greater caution, lest the point of the knife should insinuate itself through the fracture, and do mischief to the dura mater and brain.

Authors recommend the shape of the incision to be different, according to the kind of fracture and the parts of the head on which the violence has operated. When the whole extent of the injury can be brought into view, by means of an incision having the form of the letter T, the surgeon should be content with such a division; but if this be not sufficient, he may give it a crucial shape. When the trephine is to be applied to the squamous part of the temporal bone, we are recommended to make the incision as much as possible in the shape of the letter V, the branches of which are to be upwards, and the angle downwards, in order that as little as possible of the temporal muscle may be cut, and that the division of its fibres may be avoided as far as it is in our power.

Having divided the scalp, the next object is to reflect it; but no man would be warranted in cutting any part of it away, although such practice is advised by Pott. The purposes of the operation do not require any removal of this kind; and the method would leave a wound which would be long in healing, and when healed, never exempt from deformity. In short, the reflected flaps of the scalp are capable of adhering to the parts on which they are laid after the operation, and consequently ought never to be wantonly cut away.

The scalp being reflected, authors next advise us to scrape away the pericranium, either with the knife or the raspatory. Perhaps this measure may be considered as one which does neither much harm nor much good. The design is to facilitate the application of the trephine to the bone. However, the teeth of a proper instrument, in good order, will not be impeded by the slender periosteum; and scraping this membrane away from parts of the skull which are not to be removed may conduce to exfoliations.

Sometimes the bleeding from branches of the temporal or occipital artery is so copious, that the bone cannot be very conveniently perforated before the hemorrhage is suppressed. If it be prudent to wait a little, and the case (as it generally does) should be likely to be benefited by the evacuation of blood, it is as well to let the bleeding continue for a certain time. The surgeon may then just direct an assistant to put the and of one of his fingers on the mouth of the vessel, and proceed in the operation. In some cases, the bleeding might be so troublesome that it would be better to tie the artery at once.

All parts of the cranium do not admit of being trephined with equal convenience and safety. It has usually been set down by surgical authors, that the trephine cannot be applied below the transverse ridge of the os occipitis. There are some cases, however, which prove that such an operation may be safely done, and that we ought not, in urgent circumstances, to be afraid of dividing the trapezius and complexus muscles, in order to be enabled to apply the trephine to the bone.—(See *Hutchison's Case in Med. Chir. Trans. vol.* 2, *p.* 104, *&c.*)

The majority of writers also forbid the application of the trephine to the frontal sinuses, in consequence of the indeterminate depth of these cavities, and the apprehension of incurable fistulæ. However, Larrey has deviated from this precept in several instances; and his practice confirms the statement of Mr. C. Bell, that by opening the frontal sinus with a large trephine, and then using a small one, the internal parietes of this cavity may be trephined with perfect safety, and no risk of injuring the dura mater with the saw.—(See *Larrey's Mém. de Chirurgie Militaire*, *t.* 2, *p.* 136—138, *t.* 4.)

Writers also caution us not to apply the trephine to the anterior inferior angle of the parietal bone, in consequence of the middle artery of the dura mater lying under it, generally in a groove of the bone, and occasionally in a canal in its very substance. In the latter circumstance, this portion of the parietal bone could not possibly be taken away, without wounding the vessel. However, notwithstanding this advice, which has been unthinkingly handed down by one writer to another, from generation to generation, I very much question the soundness of the doctrine. We undoubtedly ought to avoid trephining this part of the cranium when we can prudently do so. But the causes demanding this operation are always so urgent, that the patient's sole chance of existence depends on their quick removal. Hence, were there pressure on the brain, either from a depressed portion of bone, from blood, or matter, and such pressure could not be removed without trephining the anterior inferior angle of the parietal bone, what operator would be afraid of doing so? Besides, the fear of the hemorrhage has been very unfounded; for the lodgement of the artery in a bony furrow or canal, which authors have pointed out as rendering the suppression of the hemorrhage more difficult, is a mere visionary idea, as it is well known that a little plug of lint, pushed into the orifice of a vessel so situated, will always stop the bleeding, with as much certainty and ease as can possibly be imagined.

The foregoing suggestion was made in the early editions of my works, and I now see the safety of the practice has been confirmed. "I have also applied the trepan (says Larrey) over the track of the sphenospinous artery, at the inferior anterior angle of the parietal bone. The artery was divided; but I stopped the hemorrhage almost immediately, by applying an iron probe red-hot."—(*Mém de Chir. Militaire*, *t.* 2 *p.* 138.)

Writers, until very lately, also prohibited us from trephining over any of the sutures, and especially over the sagittal suture, beneath which the longitudinal sinus is situated. The fear of the dura mater being injured, and of this vessel being wounded, was the reason for the advice. With regard to the sutures in general, the trephine may be applied to them as well as to any other part; and as for the sagittal suture, many facts confirm the propriety of not being deterred even by it, though situated immediately over the longitudinal sinus. It is to be remembered, also, that the dura mater, in cases of extravasated blood and matter beneath the cranium, is detached by the intervention of such fluids from the inner table.

By means of a perforation practised over the sagittal suture, Garengeot successfully elevated a portion of bone which pressed upon the longitudinal sinus, and made the patient quite comatose. The depressed piece of the cranium could not have been so advantageously raised, had the trepan been applied in any other situation. But a still stronger argument in favour of this practice, when the case at all requires it, is the fact that wounds of the longitudinal sinus, and the hemorrhage resulting from them, are not attended with any serious danger. Sharp mentions his having twice seen a bleeding of this kind. Another instance is also recorded in Warner's Cases. A child received a wound on its forehead; the two parietal bones were fractured, and a portion of each was depressed on the dura mater. The child lived a month without any operation being done; but at the end of this time Warner applied the trepan. He found a splinter of bone sticking in such a way into the longitudinal sinus, that it could not easily be got out; consequently he enlarged with a lancet the opening in which the splinter was entangled. The hemorrhage, which was copious, was easily suppressed by the application of a little dry lint, and the child was relieved, though it died at the end of two months, after suffering a variety of symptoms which had no connexion with the wound of the sinus, the opening of which soon healed. The fourth case, related by Marchettis, also proves that wounds of the longitudinal sinus are not fatal. Pott and Callisen have since reported other facts, tending to the same conclusion.—(See *Syst Chir. Hodiernæ*, *pars* 1, *p.* 659, *edit.* 1798.)

Whenever a depressed fracture can be elevated to its proper level without applying the trephine, and with the mere aid of a pair of forceps or an elevator, trephining should never be performed, unless there be strong reason to apprehend that blood, or matter, lodged on the surface of the dura mater, contributes to the production of the bad symptoms, and cannot otherwise be discharged.

The scalp having been divided, if necessary, and the pericranium scraped from the surface of the bone, according to the common precepts and practice, the next thing is the application of the crown of the trephine.

The surgeon is first to make a little impression with the point of the centre-pin, for the purpose of marking the place where it will work, when the crown of the trephine is applied in the proper situation; for where such impression is made, the operator must make a small hole with a perforator, in order to fix the point of the centre-pin, on which the crown of the instrument turns backwards and forwards, as on an axis, during the first stage of the operation. Mr. Savigny's centre-pins make a perforation, without need of any particular instrument for the purpose, and in this respect are advantageous.

The point of the centre-pin having been fixed, the trephine is to be turned by regular semicircular motions, alternately to the right and left, which object is effected by steady pronations and supinations of the operator's hand. The teeth of the saw having made a manifest circular groove, in which they can steadily work, the centre-pin becomes useless, and as it would, if not withdrawn or removed, certainly injure the dura mater and brain, by reason of its projecting farther than any other part of the instrument, it would be an unpardonable blunder to let it remain after a proper circular groove had been formed by the teeth of the saw.

The beginning of the sawing may be executed boldly and quickly; for the operator runs no hazard of doing mischief. It is necessary occasionally, with the view of facilitating the action of the instrument, to clean away the particles of bony matter with a little brush, usually kept for the purpose in every box of trephining instruments. Were this plan neglected, the action of the cylindrical saw would be very much clogged.

The operator, however, must increase his caution, when the sawing has made greater progress; for were he to be too bold, he might sometimes lacerate the membranes of the brain with the teeth of the instrument, particularly as the thickness of the cranium is subject to infinite variety, both in different parts of the same head and in different subjects. Let the surgeon, therefore, never forget to examine frequently, with the point of a quill, whether any part of the circular groove is cut through or nearly so; for when this is the case, the instrument must only be worked in such a way as to make pressure upon, and cut, the part of the circle which yet remains to be divided. In some few cases, it is said, that the surgeon can distinctly feel when the teeth of the saw reach the diploe or medullary structure between the two tables of the cranium; and some writers have rashly directed us to saw with boldness till the sensation of this occurrence is communicated to our hand and fingers. However, I believe, this possibility of discriminating the arrival of the teeth of the saw at the diploe is so uncommon and so fallacious, that it should never be expected or relied on. Nor ought the surgeon to saw with incautious force and rapidity, till he sees the teeth of the trephine bloody, which appearance has been set down as another criterion of their having reached the diploe. I have already stated, that a great many skulls have hardly any space between several parts of the two tables. This is particularly often the case in old persons.

A prudent man will always prefer exerting a little force for the purpose of breaking some of the bony connexion, retaining the circular piece of bone, to running any hazard of injuring the dura mater by sawing too deeply. After a certain time, therefore, it is better to lay down the trephine, and endeavour to elevate the portion of bone, with the aid of a pair of forceps constructed for the purpose, and kept in most cases of trephining instruments, or else by means of an elevator, which is still more calculated for the purpose.

When the circular piece of bone has been taken out, and the edges of the perforation are unequal and splintered, the irregularities are to be cut off with the lenticular knife. When there is extravasated blood underneath the opening which has been made, it sometimes spontaneously makes its escape, and if it should not do so, the surgeon must remove it himself. If one perforation of the skull should not suffice for letting out the blood, as much more of the cranium ought to be removed with the trephine as circumstances may require; there being no comparison between the danger of repeating the application of the instrument, and that of leaving a quantity of undischarged, compressing fluid, on the surface of the brain. Certainly, many facts on record evince, that the dura mater may be very extensively uncovered without dangerous consequences. Sarrau saw a whole parietal bone exfoliate, in consequence of a blow on the head. Blegny relates a similar case; and Saviard makes mention of a woman who had lost the upper part of the os frontis, both the parietal bones, and a large portion of the os occipitis, all of which had come away at the same time; yet she recovered. Vaugion, however, who seems also to relate this identical case, describes the exfoliation as not being quite so extensive.

I am of opinion, notwithstanding these facts, that exposing a large part of the dura mater with the trephine is by no means an operation exempt from serious danger. And what I conceive confirms this statement, is my having known instances, in which persons who had been rashly advised to submit to being trephined, for the cure of violent pains in the head, &c., died in consequence of the operation. I make this observation, well aware of the successful instance of the practice recorded by Schmucker.—(*Wahrnehm. b.* 1, *p.* 434.)

However, I perfectly coincide with writers who direct the removal of as much bone as is necessary in order to be able to remove the whole of the pressure from the surface of the dura mater.

The application of the trephine, in cases of large extravasations, must in particular be made several times, when the situation of the fluid does not favour its escape. But in this circumstance, Sabatier says, that we should not make numerous perforations all along the extent of the extravasation; but only a counter-opening, as is done on the soft parts. This author expresses his surprise at there not being on record many examples of counter-openings made in the cranium, since analogy demonstrates their utility. I cannot help remarking on this part of the subject, that one very obvious objection to making openings of this kind in the cranium, is the impossibility of knowing, with certainty, whether blood lies under any particular part of the skull; whereas, in abscesses of the soft parts, the surgeon feels the fluctuation of the matter, and knows that his counter-opening will be made in the cavity containing it. One may sometimes have occasion to make more than one perforation, in order to discharge blood extravasated beneath the skull, when the blow has happened near a suture, to which the dura mater continues adherent; for a single opening, made only on one side of the suture, might only give vent to a part of the extravasation.

When the trephine is applied, on account of a fracture with depression, Mr. Brodie considers the removal of a small portion of bone as generally sufficient; but when the case is an extravasation of blood on the surface of the dura mater, he recommends a freer removal of the skull. He was led to adopt this rule by having seen a case, in which, after two triangular portions of bone had been taken away with a straight saw, and a large quantity of blood discharged, to the great relief of the patient, suppuration afterward took place on the surface of the dura mater, wherever this membrane had been separated by the extravasation from the bone. The matter was hindered by the granulations from escaping by the aperture already made, and, though another portion of bone was removed, the practice was too late to save the man's life.—(See *Med. Chir. Trans. vol.* 14, *p.* 387.) Whether an extensive removal of the cranium ought to be generally made in anticipation of suppuration of the dura mater in such a case? whether such a measure might not rather tend to make the event more likely to happen? and whether the practice which Mr. Brodie actually adopted might not have been the best, though, in the instance brought forward, unsuccessful? are questions,

I think, on which the most judicious surgeons may entertain differences of opinion. As my principles lead me to disapprove of the old custom of trephining for the purpose of preventing inflammation and suppuration of the dura mater, they would incline me to be content with rigorous antiphlogistic treatment, and discharging the confined matter as soon as the ill effects of its pressure began to show themselves.

If we should not find blood lodged under the cranium, but the dura mater should seem elevated, tense, dark-coloured, forming a prominent fluctuating tumour outwards, it may be cautiously opened with a lancet or bistoury, with a view of letting out any collection of blood underneath. In the article *Head, Injuries of*, I have stated the result of Mr. Abernethy's experience, in regard to the operation of opening the dura mater. This gentleman found, that the method never effectually discharged all the blood, but only the serous part of it. The evacuation of any of the compressing fluid must, however, be desirable; and if the surgeon cannot do more, yet he has fulfilled his professional duty.

Although Mr. Brodie admits, that wounds of the dura mater are attended with great danger, he approves of the practice here recommended (see *Med. Chir. Trans. vol.* 14, *p.* 389), and supports his opinion by reference to an interesting case under the late Mr. Chevalier. This gentleman was called to a child, a year and a half old, which had received a severe blow on the head, and lay insensible and convulsed. There was no wound of the scalp; but the fontanel appeared somewhat elevated. It was therefore exposed by an incision, and raised so as to uncover the subjacent dura mater, beneath which the purple colour of extravasated blood was plainly discernible. A puncture having been made with a lancet, three or four ounces of blood issued out with considerable force; the symptoms were immediately relieved, and the child recovered.—(See *Med. Phys. Journ. vol.* 8, *p.* 505.) An example, furnishing an equally convincing proof of the practice here advised, is also adduced by Mr. Brodie from the practice of my friend and neighbour, Mr. Ogle.

The utility of trephining is not limited to discharging extravasated blood or matter lodged underneath the skull. This operation frequently enables us to elevate depressed portions of bone. The latter object can often be accomplished by merely making one perforation. Sometimes several perforations are requisite to be made near each other. Authors even state, that it may also become necessary to remove the intervening portions of bone with a pair of cutting forceps. The depressed part may then be easily raised by means of an elevator. Occasionally, indeed, I may say, very often, the best practice is to remove the depressed portion entirely, when its total separation from the rest of the skull can be accomplished by cutting across the base of the depressed piece.

According to some writers, if, after dividing the dura mater, the surface of the brain appears smooth and flabby, with a fluctuation, we may conclude there is an abscess in its substance; and these authors, more enterprising with their pens, it is to be hoped, than with their scalpels, sanction the method of carrying the point of the bistoury to the depth of an inch, *if circumstances render so deep a puncture necessary.* "But," says Richerand, "prudence forbids us to go farther. Cutting the surface of the brain causes no pain, and it produces less danger than one might apprehend; experience and observation prove (in opposition to phrenological theories), that the essential parts of this organ are situated near its base, and that *its surface may be removed without danger or pain.*" —(*Nosogr. Chir. t.* 2, *p.* 301, *ed.* 3.)

A case, in which Dupuytren plunged a bistoury to the depth of more than an inch into the brain, and thus let out an ounce and a half of pus, is recorded in a valuable periodical work.—(*See Journ. of Foreign Med. No.* 18, *p.* 298.) Some temporary amendment followed; but the case had a fatal termination.

After the operation of trephining, the divided scalp is to be placed as nearly as possible in its natural situation, and lightly dressed with a simple pledget of any common unirritating ointment. In applying the dressings, the surgeon should invariably keep in view these objects; namely, to let whatever is put on the wound be as light as possible, not apt to make pressure on the brain, and of a nature which cannot excite irritation. All stimulants are to be strictly avoided; nor will any bandage be better than an ordinary night-cap of sufficient size to be put on with facility It may be secured with bits of tape, which are to be tied under the jaw

The practitioner should not now conceive that he has done all that he ought to do. Let him remember the urgent necessity of keeping off, or diminishing, the inflammation of the dura mater and brain, which is still to be feared. Let him bleed the patient largely and repeatedly; exhibit saline purges, clysters, and antimonials; and if the symptoms continue, let him apply a blister to some part of the head. I shall avoid, however, any repetitions on this subject, by referring to *Head, Injuries of.*

The aperture in the skull usually becomes closed with soft granulations, which slowly acquire a hard consistence. While the cicatrix is soft, it should be protected from external injury with a thin piece of horn or metal. Exfoliations from the margin of the perforation sometimes retard the healing of the wound; but now that the practice of dressing with drying spirituous applications has been exploded, and the removal of any part of the scalp is condemned by all the best surgeons, these unpleasant consequences are rendered much less frequent than in former days.

The reader may find an account of the operation of trepanning or trephining in every system of surgery; but he should particularly consult the writings of Sharp, Le Dran, Dionis, Bertrandi, Pott, Sabatier Schmucker, Richter, Dease, Abernethy, Desault, Callisen, Richerand, C. Bell, and several parts of the *Mém. de l'Acad. de Chirurgie.* Also, *B. C. Brodie on Injuries of the Brain, in Med. Chir. Trans. vol.* 14.

[This article on the trephine contains perhaps the most valuable practical information any where to be found in our language. The excellent diagnosis between concussion and compression, and the valuable arguments against the indiscriminate use of the trephine, and in favour of large and repeated venesection, cannot be too familiarly known nor too highly estimated, especially by the young surgeon

It is a high source of gratification to be able to record, that in this country, the trephine is now much more seldom used than formerly. But a few years ago, on a man being stunned by a blow or a fall, to any considerable extent, almost any neighbouring physician would apply the trephine without hesitation, and the facility with which this operation can be performed, offers no small temptation to the mere operator, especially as there is seldom any risk of life, and always a gain in reputation among the multitude. It is now very generally viewed as it ought to be, as a dernier resort in such cases, and the use of it is not countenanced, unless the symptoms of compression by depressed bone, or extravasated blood, are altogether unequivocal; and a consultation with the best surgeons is always premised.

I have seen scores of persons, who would have formerly been trephined, without even a "trial by jury," recovered from coma, paralysis, and convulsions, justly attributable to compression on the brain, by very large and copious bleedings, aided by cathartics and stimulating frictions and cataplasms to the extremities.

Still, however, there will be a sufficiency of instances, imperiously requiring the use of the trephine, to render it necessary that every practitioner should be conversant with the instrument, and all the circumstances connected with its use. Indeed, some of the most deplorable cases to which surgical assistance is ever rendered, are occasionally met with among the examples in which the trephine becomes indispensable.

In the year 1819, I assisted Dr. Henry Wm. Ducachet then a practitioner in the city of Baltimore, in the performance of this operation on a woman who had received several blows on the head with an axe, from a brutal husband. We could discover no depression of bone, and yet the coma, stertor, hemiplegia, and other evidences of compression, resisted all our depletion, and on the third day after the violence, we determined to apply the trephine, being sustained by judicious counsel in our opinion, that there must be extensive extravasation of blood beneath the cranium. On removing the circular piece of bone, with the largest crown of the instrument, a coagulum was found extending over the left hemisphere of the brain, exterior to the dura mater. This being removed, and only a mitigation of the symptoms following, the obvi-

ous distention of the dura mater itself, pointed out the existence of still more extended mischief. We therefore divided the dura mater with a probe-pointed bistoury, for the space of half an inch, when coagulated blood to an immense extent forced itself through the opening. After washing out the cavity by warm water thrown in with the syringe, we were delighted to find the entire removal of the symptoms instantaneously result. Our patient spoke for the first time, asked for water, seemed as though awoke from an ordinary sleep, the stertor ceased, the dilatation of the pupil and hemiplegia were removed, and the most sanguine hopes were entertained of her recovery.

I shall never forget the painful acuteness of our disappointment, when in a few hours we found all these dangerous symptoms return in a still more aggravated form, discovering to us the mortifying truth, that *though the operation had succeeded, yet our patient would die*; for although we had removed the coagula, we could not stop the bleeding vessel.

On the post mortem examination, the temporal bone was found fractured, and a spicula of bone had pierced the meningeal artery, which had not ceased to pour out its blood, and hence, coagula were found to fill the whole space of the hemi-cranium, above and below the dura mater. I have preserved the skull in my cabinet of morbid preparations, and the point at which the fracture of the internal table pierced the great artery of the dura mater, is distinctly visible in the depression which marks its course, which is in this case deeper than ordinary. It was exhibited on the trial of the murderer, and was highly important in a medico-legal point of view, since it fully satisfied the court, counsel, and jury, that her death was occasioned by the blows, and that the injury was altogether irreparable. This was clear, from the fact that the only blows which had wounded the scalp were on the top of the head, and on the middle of the os parietalis. The fracture and consequent rupture of the vessel was low down in the temple, where no external wound was found, and two inches from the point at which the trephine was applied, guided as it was by the external injury.

Since that time, I have applied the trephine and Hey's saw for the removal of a large portion of the frontal bone, which had become carious from syphilis, involving nearly the whole forehead. The extensive suppuration which had entered the frontal sinus, and even passed into the cavity of the skull, rendered this operation necessary, in the opinion of the consultation; the man having become idiotic from the disturbance of the cerebrum, and being a burden to himself and family, from frequent epilepsy.

I applied the crown of the instrument four times, removing all the diseased portion of the bone, and only once entering through the skull, the caries being in the other parts confined to the external table, and the diploe filled with a fetid pus which had not sufficient egress, and by consequence was involving the bone still more extensively in the specific morbid action. A large number of smaller pieces of the cranium were removed with Hey's saw, and by the forceps. A very considerable quantity of pus was found upon the dura mater, at the point at which the caries had entered the cavity, which was discharged through the opening made by the trephine, and the cavity of the head washed out with warm water. Notwithstanding the specific character of the disease, the almost hopeless extent to which it had progressed, and the extreme emaciation which had been superinduced by neglect and mismanagement, this patient entirely recovered, and has ever since the time of the operation (1822) been actively employed as a mechanic; never having had epilepsy since, nor any intellectual deficiency, although this had become apparent for months before. I saw him when last in Baltimore in perfect health.

In the *New-York Med. and Phys. Journal*, *vol.* 5, *p.* 79, will be found a report of a singular case of epilepsy arising from depression of bone, cured by trephining. It was performed by my friend Dr. David L. Rogers, of this city.—*Reese.*]

TRICHIASIS (derived from θρίξ, the hair) denotes a faulty inclination of the eyelashes inwards against the globe of the eye. According to Scarpa, the disease presents itself under two distinct forms: the first is, where the cilia are turned inwards, without the natural position and direction of the tarsus being at all changed; the second consists in a morbid inclination of the tarsus inwards (*Entropium*), and consequently of the eyelash towards the eyeball (*Trichiasis*).

The first form of this disease is said, both by Beer and Scarpa, to be uncommon, nor has it come under the observation of the latter writer more than once, and, in this instance, only some of the hairs had changed their direction. On this point, however, Mr. Travers is completely at variance with the foregoing authors, as he describes an inversion of the cilia as *frequently* existing independent of entropeon.—(*Synopsis*, *p.* 232.) The second species or form of trichiasis, or that which consists in a folding inwards of the tarsus and cilia at the same time, is the case which is commonly met with in practice. It may be either complete, affecting the whole of the tarsus, or incomplete, occupying only a certain portion of the edge of the eyelid, most frequently near the external angle of the eye. Sometimes, the disease is confined to one eyelid; at other times it affects both; and occasionally the patient is afflicted with it in both eyes.

Some writers, among whom is Beer (*Lehre von den Augenkr. b.* 2, *p.* 118), admit a case, which they call *distichiasis*, and which they suppose to be produced by a double and unusual row of hairs. But, according to Scarpa, this third species is only imaginary, and the reason of this subdivision seems to have arisen from not recollecting what was long ago remarked by Winslow and Albinus, that although the roots of the cilia appear to be disposed in one line only, they form two, three, and in the upper eyelid even four rows of hairs, unequally situated, and, as it were, confused. Whenever, therefore, in consequence of disease, a certain number of hairs are separated from each other in a contrary direction and disorderly manner, the eyelash will appear to be composed of a new and unusual row of them, while, in fact, there is no change, either with respect to their number, or natural implantation.

It is not an easy matter to determine precisely, says Scarpa, what are the causes which sometimes make a few of the hairs deviate from their natural direction, while the tarsus continues in its right position. They are commonly referred to cicatrices in consequence of previous ulceration, whereby the cilia fall off, and those which are growing are hindered from taking their proper direction. There must, however, be other causes sometimes concerned; for, in the case seen by Scarpa, two or three hairs were turned inwards against the eyeball, although there had been no preceding ulceration nor cicatrices of any part of the tarsus. Indeed, Scarpa is inclined to believe, that the small ulcers and scars which are sometimes formed upon the internal margin of the tarsus, are more likely to cause the second form of the disease, or the inversion of the edge of the eyelid, and, consequently, of the cilia towards the globe of the eye. As these ulcers, when neglected, destroy the internal membrane of the eyelids near the tarsus, it necessarily follows, that in proportion as they heal and diminish, they draw along with them and turn inwards the tarsus and hairs inserted into it. And since they do not always occupy the whole extent of the internal margin of the eyelid, but are sometimes confined to a few lines in the middle or extremity near the external angle of the eyelid, so, after the cicatrices are formed, the whole of the hairs are not invariably turned inwards, but only a certain number of them, which correspond to the extent of the ulcers previously situated along the internal edge of the tarsus. Indeed, in every case of imperfect trichiasis from a cicatrix of the inner margin of the eyelid, the tarsus and cilia are every where in their natural situation except opposite the part where the ulcers formerly existed. Also, if the eyelid be everted, its internal membrane, near that part of the margin corresponding to the seat of the trichiasis, will be found pale, rigid, and hardened, the inversion of the cartilaginous border and of the cilia being plainly the effect of the contraction of the cicatrized point.

Chronic ophthalmies of long continuance sometimes bring on the complaint, in consequence of the skin of the eyelids being kept for a long time in a state of distention and œdema, terminating in a considerable relaxation of it. And, according to Beer, the too long continued use of emollient poultices may have the same effect.—(*Lehre, &c. b.* 2, *p.* 113.) The cartilaginous margin of the eyelid then loses the proper support of the integuments, inclines towards the eyeball, and afterward turns inwards, drawing the eyelashes

along with it in the same improper direction. Long-continued puriform discharges from the ciliary glands likewise spoil the shape and consistence of the cartilage of the eyelid, and therefore not unfrequently occasion trichiasis. Scarpa doubts whether a spasmodic contraction of the orbicularis palpebrarum muscle can ever be a cause of the disease.

The annoyance which must necessarily result from the hairs perpetually pressing upon the cornea and white of the eye, as Scarpa observes, may be easily imagined. The evil is rendered still greater by the hairs which are turned inwards becoming much longer and thicker than those which retain their natural direction. And although the trichiasis be confined to one eye, both the eyes usually suffer from the effects of the disease. Indeed, generally, the eye on the sound side cannot be moved without occasioning pain in that which is exposed to the irritation and friction of the inflected hairs. In almost all cases, both the eyes are very irritable, and incapable of bearing the light. As, in cases of incomplete trichiasis, the patient retains some little power of opening the eyelids for the purpose of seeing, and that most frequently towards the internal angle of the eye, the head and neck are often inclined in an awkward manner, so that in children a distortion of the neck and shoulders is at last produced, which cannot be rectified without difficulty, even after the trichiasis is cured. Unfortunately, also children are impatient of the uneasiness arising from the inflected hairs, and, therefore, are continually rubbing the eyelids, whereby all the ill effects of the complaint are much increased.

The cure of the second species of trichiasis, or that which is commonly met with in practice, is accomplished by artificially everting the eyelid, and fixing it permanently in its natural position, together with the eyelashes which irritate the globe of the eye. According to Professor Scarpa, this indication is perfectly fulfilled by the excision of a piece of the skin close to the edge of the eyelid, of such a breadth and extent that, when the cicatrix is formed, the tarsus and margin of the eyelid may be turned outwards, and sufficiently separated from the eyeball, the cicatrix of the integuments affording a point of support fully adequate to keep the parts in their natural position and direction. Scarpa believes that very few modern surgeons, with a view to the radical cure of this disease, now place any confidence either in plucking out the inverted eyelashes, bending them outwards, and retaining them so by means of adhesive plaster; or in plucking them out, and destroying their roots with caustic: much less in extirpating the edge of the eyelid along with the hairs, or dividing the orbicularis muscle on the internal surface of the eyelid, under an idea that the disease is sometimes produced by a spasmodic contraction of it.

The following is the mode of proceeding recommended by Scarpa. The patient being seated in a chair, if an adult, or, if a child, laid upon a table, with the head raised, and firmly held by an assistant, who must stand behind the patient, the surgeon is to push outwards, with the end of a probe, the hairs which irritate the eye. Then, with a pair of dissecting forceps, or the ends of his fore-finger and thumb, he should lift up a fold of the skin of the eyelid, taking great care that the piece which is taken hold of corresponds exactly to the middle of the whole extent of the trichiasis; for sometimes the whole, sometimes a half, and, in other instances, only a third of the extent of the tarsus is inverted. The surgeon, with his left hand, must raise the fold of the skin more or less, according as the relaxation of the integuments, and the inversion of the tarsus, are more or less considerable. The reason of this is evident, viz. the greater the quantity of skin is which is raised, the greater is the quantity which will be cut away. Supposing the patient to be an adult, as soon as the fold of skin has been raised in a certain degree, the surgeon must request him to open his eye; and if in this act the tarsus and eyelashes resume their natural place and direction, the portion of skin already raised will be sufficient for the purpose. When the integuments are elevated by means of a pair of dissecting forceps, and care is taken to lay hold of the skin precisely at the middle point of the whole extent of the trichiasis, it necessarily follows, that the consequent section of the skin will form an oval, and that the greatest width of the wound will correspond exactly, or nearly so, to the middle of the eyelid, and its narrowest parts to the angles, or commissures of the same. This contributes very materially to make the cicatrix correspond to the natural fold of the eyelid, and hinder the origin of the disease of an opposite nature to the one about to be remedied, towards the angles of the eye, viz. a turning out of the commissures of the eyelids.—(See *Ectropium*.)

Besides this caution, relative to the situation and figure of the fold of the integuments to be cut off, the surgeon must be careful that the division of the skin be made very near the inverted tarsus. Were this circumstance neglected, the operator might have the mortification of finding, after the wound is healed, that although the eyelid is shortened, on the whole, from the eyebrow to the place of the recision, yet it is not equally so at the space which is between the edge of the eyelid and the cicatrix of the skin. Hence, the tarsus would not be turned outwards sufficiently to keep the eyelashes from rubbing against the eye.

The surgeon, holding up the fold of skin by means of the forceps in his left hand, is, with a pair of probe pointed, sharp-curved scissors, to cut off the whole of the duplicature, being first sure that one of the blades of the instrument is applied close to the edge of the eyelid. If the eyelids should be affected, the same operation must immediately be done upon both of them, with such caution, and in such proportion, as the extent of the disease, and the degree of inversion of each eyelid may require.

Scarpa next dissuades us from employing any suture to unite the wound, and represents that it will be sufficient to keep the eyebrow as much downwards as possible, if the operation has been done on the upper eyelid, or if on the lower, to support it against the inferior arch of the orbit, by pressing it from below upwards, so as to keep the edges of the wound from becoming separated. Then the lips of the wound are to be brought exactly together by means of adhesive plaster, which should extend from the superior arch of the orbit to the zygoma; and the maintenance of this state of the wound will be still more securely effected, by placing two compresses, one on the eyebrow, and another on the zygoma, together with a bandage. On the other hand, Langenbeck disapproves of the omission of sutures, by which he finds that the wound may be both more accurately and expeditiously united. Indeed, he expresses himself generally in favour of sutures, where the wounded part is liable to be disturbed by the continual action of muscles.—(*Neue Bibl. b.* 1, *p.* 415, *&c.* 12*mo. Hanover*, 1818.) Langenbeck, however, takes care to withdraw the ligatures in about twelve, or at most twenty-four, hours, as their longer continuance would produce suppuration. Beer also particularly insists upon the utility of bringing the edges of the incision together with a suture; and both he and Langenbeck employ forceps, the ends of which have transverse pieces, calculated to take better hold of the slip of skin to be removed.—(*Lehre, &c. b.* 2, *p.* 114.)

On taking off the first dressings the third day after the operation, the surgeon will find, says Scarpa, that the patient can open his eye with ease, and that the inverted tarsus and eyelashes have resumed their natural position and direction. In the partial or incomplete trichiasis, or that which only occupies a half or a third of the whole length of the tarsus, and in subjects who have had the skin of the eyelids very loose, Scarpa has often found the wound perfectly united on removing the first dressing.

When, however, only a part of the incision has healed, while the rest seems disposed to heal by suppuration and granulation, the surgeon is to cover the wound with a small piece of lint, spread with the unguentum cerussæ; and if the sore should become flabby, it must be occasionally touched with the argentum nitratum, until the cure is finished.

With regard to the first form of this disease, or that in which the eyelashes project against the eyeball, without the natural position of the tarsus being at all altered (a case which is fortunately rare), the accomplishment of a cure is very difficult, since neither the pulling out of the hairs, nor burning the situation of their roots, are means at all to be depended upon for producing a complete cure of the disorder; and turning the tarsus out of its natural position would make the patient liable to an irremediable dropping of the tears over the cheek, attended with a chronic thickening of the lining of the eyelid. It has only been in young individuals, that Beer has ever seen the repeated and

careful extraction of the cilia effect a radical cure. —(See *Lehre von den Augenkr. b.* 2, *p.* 121.) In the instance of this form of the disease which Scarpa met with, only two or three of the eyelashes inclined against the eyeball. He found, on turning the eyelid a little out, opposite to the situation of the faulty hairs, that he could not, indeed, completely put them in their natural position; but he saw that he could thus remove them so far from the cornea, that they would not rub against it, without altering the position of the eyelids so much as to occasion a perpetual discharge of the tears over the cheek. And as, in the patient alluded to, the skin about the eyelid was very tense, Scarpa made an incision with the back of the lancet, near the tarsus, three lines long, and took away a small piece of skin of the same length, but very little more than one line broad. When the cut healed, the operation was found to answer as well as the nature of the case would allow, though the cure was not complete.

The trichiasis being cured, something more always remains to be done, for the purpose of correcting the cause of the disease, as well as curing the disorder of the eye, occasioned by the previous friction and irritation of the inverted hairs. The usual indications are to restore the tone of the vessels of the conjunctiva, to lessen the swelled Meibomian glands, and obviate opacity of the cornea.

According to Mr. Guthrie, when chronic inflammation prevails, and there is a commencing, but incomplete general inversion of the cilia, the cure of the inflammation will restore the conjunctiva to its natural state, and the cilia to their original direction, without any especial means being employed for the cure of the beginning inversion; but, when these changes proceed too slowly, the sulphuric acid, recommended by Helling, of Berlin, and Quadri, of Naples, should be applied, and will always be found effectual. Indeed, in cases where the incurvation of the cartilage is slight, and the contraction of the angles moderate, Mr. Guthrie says, that such treatment will render another operation unnecessary. Quadri applies the acid as follows: 1st. A small quantity of concentrated sulphuric acid is to be applied, by means of a piece of smooth solid wood, to the centre of the affected part of the lid, and rubbed along on an oval space, a little exceeding in length the part on which the inverted hairs are situated, and from three to four or six lines in width, according to the inveteracy of the disease. The part ought to be wiped dry, after the acid has been applied about ten seconds, in order to prevent any of it from getting into the eye. 2d. The application of the acid is now to be repeated, care being taken that it approach the edge of the eyelid, and touch the parts immediately over the inverted eyelashes; and it is to be continued, or repeated, a third or a fourth time, until the contraction of the parts draws the hair from within outwards, or to their natural situation; when the operation is completed, and the part ought to be again perfectly dried. The attachment of the cilia to the forehead by means of pieces of silk and adhesive plaster, as practised by Quadri, Mr. Guthrie very properly rejects as inconvenient and unnecessary.—(*Operative Surgery of the Eye*, *p.* 30.) Instead of sulphuric acid, Delpech applies the actual cautery.

Some new methods of performing the operation for the cure of trichiasis have been proposed by Mr. Crampton, Mr. Saunders, Dr. Jaeger, Schreger, and Mr. Guthrie. With respect to that of Mr. Saunders, however, its novelty is denied by Graefe, who states that the practice is as old as the time of Ætius.

The following is the account which Mr. Crampton gives of his plan, which he tried in one instance with complete success. "Let the eyelid be well turned outwards by an assistant; let the operator then, with a lancet, divide the broad margin of the tarsus completely through, by two perpendicular incisions, one on each side of the inverted hair or hairs; let him then, by a transverse section of the conjunctiva of the eyelid, unite the extremities of the perpendicular incisions. The portion of cartilage, contained within the incisions, can then, if inverted, with ease be restored to its original situation, and retained there by small strips of adhesive plaster, or, perhaps, what is better, by a suspensorium palpebræ, adapted to the length of the portion of the tarsus which it is intended to sustain, should one or two hairs be displaced without inversion of the tarsus."—(*Essay on the Entropeon*, *p.* 55.)

Mr. Travers informs us, that, in cases of a circumscribed inversion, "produced by cicatrix from burn or wound," he has found Mr. Crampton's method an effectual remedy. It is added, that the complete division of the conjunctiva and tarsal cartilage, including the inverted portion, and parallel to its border, with the aid of sticking plaster, sometimes proved sufficient. Mr. Travers also sees no objection to the entire removal of that portion of the tarsal edge, which is incorrigibly inverted from such a cause, especially when combined with a preternatural growth of cilia from the Meibomian border of the tarsus.—(*Synopsis*, *&c. p.* 356.) In one inveterate case, which was not effectually relieved by the frequent extraction of the cilia, cauterizing the edge of the tarsus, the excision of a slip of skin, and smearing the eyelid with concentrated sulphuric acid, as proposed by Helling (*Hufeland's Journ. st.* 4, *p.* 115), Schreger, with a pair of curved scissors, cut out a triangular piece of the cartilage of the eyelid at the place where the cilia were most troublesome. The great benefit derived from the operation then led the same practitioner to suggest the removal of the whole of the inverted edge of the tarsus, towards the inner canthus, where some irritation was yet maintained. The plan though followed by severe pain, appears to have succeeded.—(*Chir. Versuche*, *b.* 2, *p.* 253.)

Mr Saunders entertained a favourable opinion of Mr. Crampton's operation for the cure of the disease in its early stage; but he contended, that such a vicious bending of the tarsus inwards was often the consequence of repeated ophthalmy, attended with ulceration of the conjunctiva and inside of the eyelid, so that every endeavour to rectify the wrong position of the tarsus, and restore its original direction, would be fruitless. Hence, he believed that its excision was decidedly indicated; an operation which is said to be followed by no pain nor uneasiness, and which is sure in its effect. No particular shortening of the eyelid ensues; the deformity is materially lessened; and, unless the cornea be already too opaque, perfect vision is re-established. Mr. Saunders directs a piece of thin horn, or a plate of silver, having a curvature corresponding to that of the eyelid, to be introduced under this part, with its concavity towards the eyeball. On this instrument, the eyelid is to be stretched. An incision is to be made through the integuments and orbicularis palpebrarum, down to the tarsus, immediately behind the roots of the cilia. The cut should extend from the punctum lachrymale to the external angle. The exterior surface of the tarsus is then to be dissected, until the orbital margin is exposed, when the conjunctiva is to be cut through directly by the side of the tarsus, which must now be disengaged at each extremity. The punctum lachrymale must be left uninjured. The operation is described as being simple, and if any embarrassment arises, it is from the hemorrhage of the ciliary artery, the blood sometimes obscuring the punctum lachrymale, just when the operator is about to divide the tarsus by the side of it. No dressings are required, it being merely necessary to keep the eye covered for a few days. The skin will continue to be elevated, just as the perfect eyelid was; and, though less completely, yet enough to leave the pupil clear, when the eye is moderately directed upwards. In all the cases in which Mr. Saunders operated, a fungus grew from the wound. He recommends the excrescence to be destroyed with caustic or the knife.

Respecting this operation, I shall merely observe that it is more severe than that advised by Scarpa, and even than the method of Schreger, and must leave greater disfigurement. Unless, therefore, the latter methods prove ineffectual, I should consider the practice unjustifiable. Mr. Guthrie has seen three persons, on whom this operation had been performed, and on two of them by Mr. Saunders himself: in all, the deformity was considerable, and the relief only partial.—(*Operative Surgery of the Eye*, *p.* 25.) Nor is Schreger's method allowable, except in cases which resist the milder plan, sanctioned by Beer and Scarpa.

Mr. Guthrie recommends the following operation, as adequate to the cure of the worst cases. A small narrow knife, or one blade of a blunt-pointed scissors, is to be introduced close to the external angle, and a perpendicular incision made, from a quarter to half an inch in extent, or of sufficient length to render the eyelid quite free. Another incision is then to be made,

in a similar way, at the inner angle, without including the punctum lachrymale. "The length to which the perpendicular incisions at both angles ought to extend must now be decided upon by the appearance of the part; they must be continued, if necessary, by repeated touches with the scissors, until that part of the eyelid containing the tarsal cartilage is perfectly free, and is evidently not acted upon by the fibres of the orbicularis muscle." The part included in the incisions is now to be completely everted, and retained by the fore-finger of the operator's left hand against the patient's brow; when, if any lateral attachment be observed, confining the lid, it is to be divided. "On letting the eyeball fall on the eye, the edge of the tarsus and the hairs will frequently appear in the natural situation, in consequence of the relaxation of the angles which bound them down; but if the tarsal cartilage has become altered in its curvature, this will be immediately perceived; it will turn inwards at its ciliary edge, and be completely bent at its extremities, more especially at the inner one, where it is more powerfully acted upon by the ciliaris muscle. On desiring the patient to raise the lid, he readily attempts it, but the action of the levator, in such cases of vicious curvature, causes the cartilage to resume its situation; and on examination the curve will be observed to be so permanently vicious, for about an eighth of an inch at each extremity, and especially at the inner, that it cannot be induced to resume its actual situation. When this is the case, the cartilage is to be divided exactly at the place where it is bent in its length, and in a direction at a right angle with the perpendicular incision: the portion thus slit is only connected with the common integuments of the eyelid; and although this incision scarcely exceeds one, and never two, eighths of an inch, at both extremities, and in general is only necessary at the inner, it enables the surgeon to remove the altered curvature of the part." The next proceeding in Mr. Guthrie's operation consists in cutting away a fold of skin from the part of the eyelid between the incisions. Three or four ligatures are then to be introduced, and the divided parts, from which the fold has been removed, are to be brought together by the ligatures, each of which is to be twisted and fastened to the forehead with several short strips of sticking plaster. The fold of skin should be raised regularly with the fingers, and as near as possible to the margin of the eyelid. It may then be taken hold of with Beer's forceps, the grasping pieces of which are transverse, slightly curved, and shut with a spring. The skin thus taken hold of, which need not be large, may now be cut away with a large pair of curved or straight scissors. The ligatures are first inserted at each angle, and when the vicious curvature is considerable, Mr. Guthrie not only passes them through the skin, but takes care to make the *internal one* include, at its lower part, the *outer edge* of the margin of the eyelid. The ligatures, thus placed, are to be equally drawn up on the forehead, until the eyelid is *completely everted*, when they are to be fastened in the manner above specified. In order to prevent union by the first intention, and make the granulating process necessary, the edges are slightly touched with the sulphate of copper. The eye and eyelids are now to be carefully cleansed; a piece of lint, spread with the ung. cetacei, is to be placed upon them; a small compress under the edge of the orbit; and a retaining bandage over the whole. The next morning the bandage and lint are to be removed, the eye fomented and cleansed, and the dressings replaced. On the second day, great care must be taken that the ligatures keep the lid sufficiently raised; and if any union has taken place by adhesion at the angles of the incisions, it must be broken through with the probe. On the third day, the plasters on the forehead should generally be changed. The ligatures themselves must be supported by straps of plaster, placed vertically between them; and the edges of the incisions should be touched again with the sulphate of copper, or separated with a probe. In a few days more, the ligatures cut their way out; and by the time the parts are healed, the eyelid will have resumed its natural situation.—(*Operative Surgery of the Eye*, *p.* 31, *&c.*) Operations on the same principle are also recommended by Mr. Guthrie for the lower eyelid.

When a surgeon chooses to try the foregoing operation, he ought to be certain that the cartilage of the tarsus is so altered in its shape as not to afford much chance of effectual relief from milder plans.

Inversion of the lower eyelid is much less common than that of the upper one. The late Mr. Saunders never saw this disease arise from the same causes which induce it in the upper eyelid, though he acknowledges the possibility of such a case. However, he met with several instances of the affection in consequence of encysted tumours, which, as they increased, carried the orbital edge of the tarsus outwards, and in the same proportion inclined the ciliary edge towards the globe of the eye.

An inversion of the inferior palpebra is sometimes produced by inflammation and swelling of that part of the conjunctiva which connects the eyelid with the eyeball. In cases of ophthalmy this membrane often forms between the latter parts a distinct fold, which is situated just on the inside of the orbital edge of the tarsus, and pushes it outwards; while the contraction of the orbicularis muscle turns the ciliary edge inwards, and inclines it between the swelling of the conjunctiva and the eye. In this particular case, Mr. Saunders assures us that replacing the eyelid in the early stage of the disease, and maintaining it so until the ophthalmy has been lessened by proper means, will be found effectual. But when the conjunctiva is much thickened and indurated, Mr. Saunders recommends cutting such diseased part of it away, and the application of compresses to keep the orbital margin of the tarsus inwards.—(See also *Travers's Synopsis*, *p.* 234 *and* 355.)

Albinus has recorded a species of trichiasis, which originated from the growth and inversion of one of the hairs upon the caruncula lachrymalia. The plan of relief consisted in plucking out the irritating hair but it is not mentioned whether it grew again.

TRISMUS. (From τρίζω, to gnash the teeth.) The locked jaw. See *Tetanus*.

TROCHAR, or Trocar. (From the French, *trois quart*, three-fourths, from its point being of a trian gular form.) An instrument used for discharging aqueous fluids, and now and then matter from different cavities in the body, particularly those of the peritoneum, and tunica vaginalis, in cases of ascites and hydrocele. Trocars are also employed for tapping the bladder, dropsical ovaries, &c.

A trocar consists of a perforator or stilet, and of a cannula, which is so adapted to the first piece of the instrument, that when the puncture is made, they both enter the wound together with perfect ease, after which, the stilet being withdrawn, the cannula remains in the wound, and gives a ready passage for the fluid outwards.

Such are the uses of a trocar, and the principles on which it should be constructed. It would be unnecessary in this work to detail every little particularity in the instrument. I shall merely observe, that the trian gular-pointed trocars seem to retain the greatest share of approbation; for, although those of a flat lancet-pointed shape enter parts with more ease, their cannulæ are not large enough for the ready escape of fluids which are at all thick, gelatinous, or blended with fy datids, and flaky substances.

The trocar for puncturing the bladder from the rec tum should be longer than a common trocar and of a curved form; but, as Mr. Carpue has explained, it should not be passed too high up the rectum, lest the peritoneum be wounded.

Surgeons ought always to have at least three trocars

one of full size, another of middling width, and a third of small dimensions. In cases of hydrocele, the latter is often preferable.

TRUSS. (*Trousse*, French.) *Brachierium*. A bandage or apparatus for keeping a hernia reduced. A truss which fulfils its intention properly should compress the neck of the hernial sac and the ring, or external opening of the hernia, in such a manner, that a protrusion of any of the contents of the abdomen will be prevented with complete security. Hence, it is the indispensable quality of a good truss first to make effectual and equal pressure on the parts indicated, without causing pain or inconvenience to the patient; secondly, not easily to slip out of its right situation, in the varying motions and positions of the body.

Trusses are either of an elastic or non-elastic kind. The latter are composed of leather, fustian, dimity, or similar materials. These cannot be at all depended on, and should therefore be entirely banished from surgery. Since (as Mr. Lawrence has remarked) the size of the abdomen varies according to the different states of the viscera and to the motions of its parietes in respiration, a non-elastic bandage must vary constantly in its degree of tightness, and keep up either too great or too little pressure. The omentum or intestine easily slips out when the opening is not exactly closed, and the patient who wears such a bandage must be in a state of constant insecurity. Those who lead an active life, or are obliged to use laborious exertions, will be more particularly exposed to risk. If the patient, after experiencing these defects, endeavours to remedy them by drawing the bandage tighter, he may confine the viscera, but he produces other inconveniences. The increased pressure injures the spermatic cord, and may affect the testicle; the integuments become red, painful, and excoriated: and the bandage must be entirely laid aside until the parts have recovered. Richter has often seen painful tumefaction of the testicle, hydrocele, and even cirsocele, produced from this cause, and entirely dissipated by the employment of a proper truss.—(*Traité des Hernies*, *p.* 24.) He also saw the pad of a non-elastic bandage excite in the region of the abdominal ring a considerable inflammation, which terminated after a few days in suppuration. The hernia never appeared again after the cure of the abscess. The inflammation had extended to the neck of the sac and obliterated that part.—(*On Ruptures*, *ed.* 3, *p.* 69, 70.) The *spring* is a very essential part of every elastic truss, and it consists of a flat long piece of steel, which is adapted to the side of the body on which the hernia is situated. It is not a great many years since the spring used to be made of common iron, and Arnaud and Richter express their preference to a mixture of malleable iron and steel, so that the instrument may be moulded by the hand to any particular shape; but, as Mr. Lawrence well observes, a truss which admits of such management must be more or less liable to the objections which apply to inelastic bandages, and the only material which possesses the requisite qualities of firmness and elasticity, is well-tempered steel. The front part of the steel spring has an expanded form, and when the truss is properly applied, ought to be situated over the mouth of the hernial sac. The spring of a truss has commonly been a semicircle, with the posterior end resting on the spine. Camper proposed to carry it round to the anterior superior spine of the ileum on the sound side; a plan of which Scarpa highly approves. Trusses of this form fit with a degree of steadiness, which cannot be given to others by tightening the strap. They keep up the rupture better than even a stronger spring of the common kind. Under the back surface of the anterior end of the spring is placed the pad, which should be adapted in shape and size to the passage which is intended to be shut up. The steel spring is usually covered with leather, is lined with soft materials, and after being put on the patient, is fastened in its situation by means of a strap, which extends from the two ends of the spring round that side of the body on which the hernia is not situated. Hare-skin, with the fur outwards, is sometimes considered the best covering for preserving the spring from the ill effects of perspiration.

When it is necessary to make strong compression, as in large old ruptures and in persons who cannot avoid labour and exercise, the elastic spring should be made accordingly thicker and broader. But an object of the first-rate importance is to make the spring press equally upon every point of the body which it touches. This is what demands the earnest attention both of the surgeon and the instrument-maker, especially as the hips of some individuals are flat and narrow, while those of other persons are broad and prominent. A thick, flexible, metallic wire, accurately applied round the pelvis, will serve to take the measure and proper shape of the spring, which may afterward be altered a little if found necessary. The wire, however, should be somewhat longer, on account of the length of the spring.

The springs of trusses intended for children and persons who do not undergo much labour and exertion, need not be made so strong as those designed for hard-working, active people.

The idea that children cannot wear steel trusses is as erroneous as it is dangerous in its practical consequences; a point on which Mr Pott has strongly insisted.

Trusses are sometimes fabricated with a pad moveable on the spring instead of being riveted to it. This may be inclined upwards or downwards according to the form of the abdomen; and it is retained at the desired point by a spring fitting into the teeth of a rack. In others, the plate contains a screw, by which the cushion is pushed farther inwards, or allowed to recede at pleasure. Although there cannot be a doubt that some of these inventions possess considerable merit, and are in certain instances superiorly useful, it must be confessed that in general their utility is not so much greater than that of common pads, as to make amends for the want of simplicity and the increase of expense. I should be sorry, however, to say any thing that would unfairly discourage all such ingenious endeavours to improve an instrument so difficult to bring to perfection as a truss; especially as I believe there are particular cases in which pads with racks, screws, springs, &c may be employed with great advantage.

Notwithstanding every care, sometimes even elastic trusses cannot be hindered from slipping away from the part which they are designed to compress. Sometimes they slip downwards, which in fat subjects is generally caused by the projection of the abdomen. Occasionally, the fault consists in the instrument becoming displaced in the direction upwards, which mostly happens in thin persons, and is produced by the flatness of the abdomen. In the first case, the displacement is to be prevented by the use of an elastic scapulary; in the second, the slipping of the pad upwards is to be prevented by the employment of a thigh strap.

When a patient is afflicted with a rupture on each side, the two protrusions may be very well kept up by means of a single truss made with two pads, which are joined together at the exact distance of the rings from each other by a piece of steel, applied over the convexity of the symphysis of the pubes, and proportioned in length to the space between the two openings through which the viscera descend. In such cases, however, it is absolutely necessary to have the spring stronger than if there were only one rupture. The truss should also be put on that side of the body upon which the hernia most difficult to retain is situated. Some practitioners, however, give the preference to the use of two single trusses joined together in front and behind with suitable straps.

With respect to the application and use of trusses, the following instructions seem to merit attention.

1. A truss should never be first applied, or changed, except when the patient is in the horizontal posture, and it is known with certainty that all the contents of the rupture are completely reduced.

2. The first applications of a truss should always be made under the superintendence of the surgeon himself; and care should be taken to put on the instrument in such a manner that the lower third of the pad will compress the neck of the hernial sac against the os pubis, while the upper portion will compress the abdominal ring. The surgeon should also make the patient acquainted with the right manner of applying the truss; the principles on which it keeps up the bowels, and affords a chance of a radical cure; the requisite cautions to be observed, &c. When a patient first begins to wear a truss, he should be particularly careful not to be guilty of any imprudent exertions,

and it behooves him to observe most attentively, that the instrument does not slip from its proper situation. It will also be necessary for him to pay attention to the instrument being neither too tight nor too loose.

3. The patient ought to be provided with at least two trusses, which should be changed every morning in bed. In order to save the truss, especially in fat persons who perspire a great deal, it is a good plan to lay a soft piece of calico under the pad.

4. An uneasiness about the ring, which always gives rise to a suspicion that a portion of intestine or omentum is protruded, makes it proper to take off the truss, carefully examine the parts, and reduce them if they have descended.

5. When the skin is excoriated by the truss, the part may be cured by sprinkling upon it the powder of acetate of lead, fullers' earth, lapis calaminaris, &c., or bathing the part with an astringent lotion. It will also be right to protect the excoriated place with a piece of linen put under the truss.

6. When the pressure of the truss excites affections and swellings of the spermatic cord and testicle, either the thigh-strap must be relaxed or the lower part of the pad made less prominent. And when strong pressure is absolutely necessary to keep the hernia reduced, the pad should have an excavation in it over the spermatic cord. Whoever wears a truss should be careful to employ it day and night without interruption, so that there may be no opportunity for the hernia to protrude again. If, under the employment of a truss, the rupture once descends again, either a strangulation happens from the narrowness of the neck of the sac, or at all events, the hope of a radical cure, which may have been entertained for years and months, is destroyed in a moment; for experience has put it beyond all doubt, that by the continual unremitted use of a truss, and the steady retention of the contents of the hernia, the neck of the hernial sac and the ring may be gradually lessened in diameter, until they are entirely closed, and a radical cure of the rupture effected. This is more frequently observed in young subjects, seldom in adults, and scarcely ever in persons of advanced years. But trusses must be worn a long while; nor should the patient venture to lay aside their use till after many cautious attempts; beginning the experiment at first only in the night-time, and not making it in the day till after a considerable period from the time when he first thinks himself safe. The longer and more attentively a truss is worn, the greater is the hope of a radical cure.—(*Callisen, Syst. Chir. Hod. t.* 2.)

In the last edition of the *First Lines of the Practice of Surgery*, the truss for navel ruptures, which was devised by Mr. Eagland, and latterly preferred by Mr. Hey, is described; and in the article *Hernia* an account is given of the truss for umbilical hernia, invented by Mr. Marrison, of Leeds, and described by Mr. Hey. In the same part of this Dictionary may also be found some observations relative to the place against which the pressure of the pads of trusses should be directed in cases of inguinal hernia, in conformity to Sir A. Cooper's description of the situation at which the parts first protrude from the abdomen.

[The truss of Salmon, Ody, & Co., of London, formerly obtained a preference in this country, amid the multitude of modifications to which this instrument has been subjected. And, indeed, very little was taught or known among surgeons in reference to this instrument, its construction and application being intrusted for the most part to the mechanic and to the patient, until within a few years.

Our profession is very largely indebted to Dr. Amos G. Hull, of New-York, for the valuable service he has rendered the cause of humanity as well as the science of surgery, by the indefatigable labours, and persevering ingenuity which he has devoted to this interesting department of chirurgery. After experiencing in his own practice the defects of the various kinds of trusses ordinarily employed, and suffering the inconveniences of which surgeons and patients have so long complained, he was induced to attempt the construction of an instrument, which should fulfil the surgical indications in the treatment of reducible hernia; an object which seemed to have been overlooked by previous inventors, and to accomplish which a knowledge of the anatomy of the parts, and the mechanical operation of the truss was alike indispensable.

Dr. Hull brought to this subject a mechanical genius of more than ordinary acuteness, and at the same time an intimate and accurate knowledge of the intricate subject of hernia itself, and succeeded in constructing an instrument which is not only applicable to every species of rupture to which a truss is adapted; but, in recent cases, and young children, is fully adequate to effect a radical cure, as proved by experience and attested by the leading surgeons of the present day.

I shall not describe the improvements and modifications to which Dr. Hull subjected his invention before it arrived to its present degree of perfection, nor speak of the difficulties he has encountered in introducing it into general use, and acquiring for it an almost universal preference. He has, however, at once an apology and justification for his having patented the instrument, thus deviating from what is considered ordinarily professional, in the fact, that base and servile imitations of his instrument would otherwise have deprived the profession and the world of the improvement itself, by bringing it into disrepute. This has already been a subject of painful interest to Dr. Hull and his professional friends, apart from its manifest injustice to the inventor. Numerous innovations and modifications have been resorted to with a view of appropriating the surgical principles embraced in the instrument of Dr. Hull, by those who construct their trusses of inferior materials, and otherwise defeat the utility and success of the invention.

Dr. Hull claims for himself the merit of accomplishing the true indications in the surgical treatment of reducible hernia, by the four following distinctive peculiarities embraced in his truss, viz.

1st. The *concave* internal surface of the *rupture pad*, from its pressure being greatest at the *circumference*, tends constantly to approximate the hernial parietes, affording them rest and mechanical support.

2d. The combined hinge and pivot mode of connexion between the *spring* and *pad*, by means of a tenon and mortice so constructed as to preserve a *double hinge* and *limited joint* acting in every direction, thereby securing the uniform pressure of the spring on the pad, and sustaining the same nice coaptation of the pad and rupture opening, as well under the varied ordinary muscular actions as when the body is in a recumbent posture.

3d. The graduating power and fixture of the pad to the spring, rendering, as will be readily perceived, the condition of the pad perfectly controllable, even to nameless minuteness. Also resulting from this mechanism is the advantage of accommodating a large truss to a small person; hence the facility of supplying, without disappointment, persons at a distance.

4th. The double inguinal truss being simply the addition of another pad attached to a short elastic metallic plate: this plate with its pad move on the main spring by the same power of adjustment and fixture as the first pad, the pressure of the pads being graduated at pleasure by an intervening cork wedge.

In the article *Hernia* I have hinted at the importance of a *concave* rupture pad, instead of a convex one, so universal and once thought indispensable. It is no marvel that so few radical cures were ever known by the truss, when the *convex* pad of the instrument was fitted to the mouth of the rupture, thus enlarging the hernial opening. By this instrument, the elevated circular margin of the concave pad is made to approximate the sides of the hernial opening, closes the aperture, and hence results in a permanent cure of the disease. I have known many instances of radical cures by this instrument, and in some of them the truss has been laid aside for several years without the smallest return of the disease. It is to the interest of the profession universally to become acquainted with this instrument, and to profit by its superiority.—*Reese.*]

TUMOUR. A swelling. In considering all the various tumours and indurations which occur in inflammation and disease, no doubt, the processes by which they are formed must be attended with considerable diversity. Yet, as Dr. Armstrong has remarked, the general principles of morbid changes of structure may admit of being reduced to a small number. Thus, says he, if we take the acknowledged products of inflammation, and to them add tubercle, scirrhus, fungus, and melanosis, we have at once a bird's-eye view of the most important changes which occur in the solids.—(See *Morbid Anatomy of the Bowels, &c. p.* 1.)

In the present article, I intend only to treat of what are usually called sarcomatous and encysted tumours. Mr. Abernethy thinks, that the manner in which tumours are formed is best illustrated by those which hang pendulous from the membranous lining of different cavities. This gentleman adverts to an example noticed by Mr. Hunter, in which, on the cavity of the abdomen being opened, there appeared lying upon the peritoneum a small portion of red blood recently coagulated. This, on examination, was found to be connected with the surface upon which it had been deposited, by means of an attachment half an inch long, and this neck had been formed before the coagulum had lost its red colour.—(See *Trans. for the Improvement of Med. and Chir. Knowledge*, *vol.* 1, *p.* 231.) Mr. Abernethy observes, that if vessels had shot through the slender neck, and organized the clot of blood, this would then have become a living part: it might have grown to an indefinite magnitude, and its nature and progress would probably have depended on the organization which it had assumed. He mentions his possession of a pendulous tumour found growing from the surface of the peritoneum, and which was undoubtedly formed in the same manner as the tumour noticed by Mr. Hunter, viz. by vessels shooting into a piece of extravasated blood or lymph, and rendering it a living organized substance. Tumours in every situation, and of every description, are probably formed in the same way. The coagulating lymph being effused, either accidentally or in consequence of disease, is afterward converted into a living part, by the growth of the adjacent vessels and nerves into it. Mr. Abernethy remarks, that when the deposited substance has its attachment by a single thread, all its vascular supply must proceed through that part; but in other cases, the vessels shoot into it irregularly at various parts of its surface. Thus an unorganized concrete becomes a living tumour, which has at first no perceptible peculiarity as to its nature. Although its supply of blood is furnished by the vessels of the surrounding parts, it seems to live and grow by its own independent powers, while its future structure seems to depend on the operation of its own vessels. Mr. Abernethy conceives, that the altered structure of an enlarged gland affords no contradiction to the above account, as in this latter case the substance of the gland is the matrix, in which the matter forming the tumour or enlargement is deposited. The structure of a tumour, he observes, is sometimes like that of the parts near which it grows. Such as are pendulous in joints are cartilaginous or osseous. Fatty tumours frequently form in the midst of the adipose substance, and he has seen some tumours growing from the palate which had a slender attachment, and resembled the palate in structure.

However, this resemblance of the structure of a tumour to that of the neighbouring parts is not always observable. I have in my own possession a completely cartilaginous tumour, which I found in the midst of the fat near the kidneys. The pendulous portion of fat growing from the peritoneum, and mentioned by Mr. Abernethy, serves as another instance of the fact; and one might add, that every polypus which we meet with bears no resemblance in structure to the neighbouring parts. He has seen bony tumours which were unconnected with bone or the periosteum, and he observes, that the structure of a tumour is in general unlike that of the part in which it is produced.

When the coagulable part of the blood is effused, and the absorbents do not take it away, the surrounding blood-vessels are supposed to grow into it, and convert it into a vascular tumour. The effusion of the coagulable part of the blood may be the effect of accident, or of a common inflammatory process, or it may be the consequence of some diseased action of the surrounding vessels, which diseased action may influence the organization and growth of the tumour.

In the former cases, the parts surrounding the tumour may be considered simply as the sources from which it derives its nutriment, while it grows apparently by its own inherent powers, and its organization depends upon actions begun and existing in itself. If such a tumour be removed, the surrounding parts, being sound, soon heal, and a complete cure ensues. But if a tumour be removed, whose existence depends on the disease of the surrounding parts which are still left, and this disease be not altered by the stimulus of the operation, no benefit is obtained. These parts again produce a diseased substance, which has generally the appearance of fungus, and, in consequence of being irritated by the injury of the operation, the disease is in general increased by the means which were designed for its cure. It appears, therefore, that in some cases of tumours, the newly-formed part alone requires removal, while in others the surrounding substance must be taken away, or a radical cure cannot be effected.—(*Abernethy's Surg. Obs.* 1804.) This gentleman conceives, that the irritation of the tumour itself, when once the swelling has been produced, keeps up an increased action in the surrounding vessels, so as to become a sufficient cause of the disease continuing to grow larger. As the tumour becomes of greater magnitude, it condenses the surrounding cellular substance, and thus makes for itself a sort of capsule. The close or loose manner in which tumours become connected with the surrounding parts, seems to depend very much on the degree of irritation and inflammation excited in the circumjacent parts. When a tumour has been at all tender, painful, and inflamed, it is generally found intimately adherent to all the neighbouring parts. Mr. Abernethy also believes, that the increased irritation which a tumour creates, when it has exceeded a certain size, may explain why some tumours, which are at first slow in their progress, afterward begin to grow with great rapidity.

The process by which tumours are formed is commonly thought to be attended with an increased action of the vessels which supply them with blood. It is supposed, in short, to be the same kind of process which forms all the thickenings and indurations, which under various circumstances occur in different parts of the human body. It has sometimes been named *chronic* inflammation, to distinguish it from that which is more quick in the production of certain effects, and is often attended with a manifest throbbing in the part affected. This subject of chronic or passive inflammation is one about which very little certain is known; and even the name itself has commonly been admitted only on the supposition, that some kind of increased action exists in the vessels, though of a slower and less evident kind than what prevails in acute inflammation. According to Dr. Wilson Philip, the difference between what is called active and passive inflammation, seems to depend upon "the degree in which the arteries supplying the *vis à tergo* to the debilitated vessels are excited."—(*Laws of the Vital Functions*, *p.* 282, *edit.* 2.) If this position be satisfactorily established, one important step will be made to a knowledge of the differences between acute and chronic inflammation, but much would yet remain for explanation, before our ideas of the latter process would be at all complete.

In a work of considerable merit, Dr. Baron, of Gloucester, offers many considerations against the correctness of the ordinary doctrines respecting the formation of tubercles and tumours. By *tubercles*, he means disorganizations composed of one cyst, "whatever be its magnitude, or the nature of its contents;" and by *tumours*, he would understand "morbid structures, that appear to be composed of more than one tubercle."—(*On Tuberculated Accretions of Serous Membranes*, *&c. p.* 213.) From certain appearances traced in dissections, Dr. Baron infers, that all tubercles, wherever situated and of whatever substance composed, were at their commencement small vesicular bodies, with fluid contents; hydatids, as he endeavours to prove. "It is impossible to say how minute they may have been at their origin, or how large they may grow before their transformations begin; nor are we acquainted with the circumstances which occasion such transformations." To these *changes* in hydatids (according to this writer), certain tubercles owe their existence, and "on the *size*, *relative position*, and *structure of the tubercles*, *which are so formed*, *depend the characters of many of the most formidable disorganizations* to which the human body is exposed."—(*P.* 215.) A single hydatid, when it is transformed (says Dr. Baron), will give rise to one tubercle. "It may be pendulous, or imbedded in any soft part, or it may be found between the layers of membranes, and wherever the textures are of such a nature as to admit of its growth. It may be so small as to be scarcely visible, or it may acquire a very great magnitude. Single tubercles are often seen in a viscus, while all the rest of the organ is

free from disease, and its functions are performed in an uninterrupted manner. But it is evident that the same state of the system (whatever that may be) which calls one tubercle into existence, may generate an indefinite number. They may be diffused through the whole of a viscus, leaving nothing of its original texture, or they may occupy any proportion of it, or extend to the contiguous parts, and involve them in the same form of disease."—(*P.* 216.) When hydatids, growing in clusters and hanging within cavities, become changed into tubercles, Dr. Baron conceives that the morbid appearances must of course correspond, in some degree, with the original distribution of the parts. He has seen tubercles attached in this form to the choroid plexus, to the valves of the heart, to the fimbriated extremities of the Fallopian tubes, and to the omentum and convolutions of the bowels. In the latter instance they were very minute, the largest not being bigger than the head of a pin, and their number defied all calculation.

"Other varieties in the arrangement of the elementary parts of morbid growths will of course cause corresponding varieties in their appearance. Thus, *when hydatids are enclosed the one within the other, and are transmuted into solid substances, a section of these substances will exhibit a series of concentric lamina.*"

Another variety pointed out by Dr. Baron is, "when an immense number of very small tubercles are generated in juxtaposition, and unite together. Wherever such an event occurs, the original texture of the part is entirely lost, and a mass of varying degrees of density and firmness formed. In the earlier stages of its growth, a granulated appearance may be distinctly traced; but in process of time this disappears, the consolidation becomes more complete, and substances of a gristly, or cartilaginous, or scirrhous texture may be found. I have traced (says Dr. Baron) the whole of these gradations in the liver, the lungs, the pleura, the omentum, the peritoneum, and in tumours in other parts."—(*P.* 219.)

"Sometimes small hydatids grow from the outer or inner surface of large ones, or float within them. I have seen (says Dr. Baron), from a source of this kind, the uterus and its appendages converted into an enormous misshapen mass, tubercles of the size of the fist growing from it, while these again were surmounted by smaller ones in many gradations. Some had glairy contents, others were in a state of scirrhosity, and others were but little changed, having thin delicate cysts, and containing a transparent fluid.

"But perhaps (remarks Dr. Baron) the most important variety of all is, when tubercles, originally distinct from each other, approximate as they increase in size, ultimately unite, and form tumours, which have received different designations, according to the predominant character of their contents and internal structure. It was chiefly to elucidate this part of the subject, that I made the distinction between the words tumour and tubercle," &c.—(*P.* 219.) By thus adverting to the primitive arrangement, number, size, &c. of hydatids, and their subsequent mutations, Dr. Baron tries to account for the varieties of encysted and sarcomatous tumours, fungus hæmatodes, tuberculated sarcoma, scirrhous swellings, &c. &c. The late Dr. Adams, as is well known, referred cancer to the living state, growth, and multiplication of the hydatid.—(*On the Cancerous Breast, p.* 77.) In order to account for the various appearances of the disease, he has divided hydatids into a number of species, as *lymphatica, cruenta*, and *carcinomatosa*, and suspects that there may be others. These, he affirms, are lodged in different cavities, or enclosed in a fungus, which is occasioned by any individual or numbers, stimulating the surrounding parts to generate it, for the purpose of dividing the dead from the living. This fungus is a nidus, formed altogether for the protection of another generation; by means of it, the living families are separated from the dead, and their preservation is secured. They die, he says, without otherwise affecting the body in which they existed but by their local stimulus, and he declares that his object is to prove the *animalcular existence* of carcinoma. Now, according to Dr. Baron, this main position is the fundamental error of Dr. Adams's book; for "in no rational nor legitimate point of view may cancer be said to have an *animalcular existence*; because admitting, for the sake of argument, that hydatids are animalcules, it has, I trust, been shown (says Dr. Baron) that *it is to the loss of the hydatical character altogether, and the transformations of these bodies, that the morbid appearances in this and many other diseases, are to be referred.*"—(*P.* 276.)

Although I consider the evidence and remarks which Dr. Baron has adduced in support of his opinions in many respects interesting, the facts brought forward do not appear to me to justify the conclusion, that the formation of tubercles and tumours originally depends upon hydatids and their transformation. That hydatids are sometimes found within diseased structures, and that cells, cysts, granulated and tuberculated appearances are often noticed in tumours of different kinds, are facts universally received. But the presence of hydatids in the *unchanged* state is only an occasional circumstance; whereas, if they were generally a cause of tumours by undergoing some unexplained transformation, it is impossible to suppose, that some of them at least would not be more commonly found in a distinct, unaltered form within or around all swellings imagined to proceed from clusters of them. As the growth of tumours formed on these principles could not, I imagine, be accounted for without supposing a continual multiplication and transformation of hydatids, either within or around the swellings, one would expect that some visible hydatids, previously to their transfiguration, would certainly be apparent on minutely examining the interior and the circumference of the diseased structure. Yet I am not aware that such fact has been proved to be generally the case, either by the aid of the scalpel or the microscope. The observation of cavities, cells, and tuberculated appearances in some kinds of tumours, is no proof that such modifications of structure are transformed hydatids. Besides, if my limits would allow me to consider this topic farther, many reasons might be urged against the hydatid doctrine, arising from the consideration of the changes evident in the blood-vessels supplying parts in which a considerable tumour is situated. Thus we often see the trunks of the arteries running towards such parts, doubled in size, as is noticed with respect to the carotid in the natural growth of the stag's horn, and indicating, at least, that the formation and increase of swellings are effected through the medium of the blood-vessels. The sudden effect of tying the arteries by which a tumour is supplied with blood, would also be difficult to explain, if the growth of the swelling really depended upon some undefined transformation of hydatids.

It seems to be generally admitted, that the growth of all tumours may be retarded, and that sometimes they may even be diminished by means of topical bleeding with leeches, and keeping the parts in a continually cool state by the incessant application of cold sedative washes. Afterward, when the increased action of the vessels seems checked, and the tumour ceases to enlarge, discutients are indicated, such as frictions with mercurial ointment, pressure, electricity, rubefacient plasters, solutions of salts, blisters, and issues. Very few sarcomatous or encysted tumours, however, are ever completely removed by these local means. The swelling, on the contrary, generally increases, notwithstanding them; and the irritation of the disease by stimulants is not altogether unattended with danger of the affection becoming changed by them into very malignant and dangerous cases, sometimes to all appearances cancerous. The most advisable plan is to recommend the removal of sarcomatous tumours with the knife, while they are small and in an incipient state; for thus they are got rid of by an operation which is certainly trivial, compared with what might afterward become requisite, if the disease were allowed to proceed, and attain an enormous magnitude.

TUMOURS, SARCOMATOUS. These have been so named from their firm, fleshy feel. They are of many kinds, some of which are simple, while others are complicated, with a malignant tendency. Mr. Abernethy has attempted to form a classification of sarcomatous tumours, for the different species of which he has proposed names, deduced from the structure which they exhibit on dissection. This gentleman has named the kind of swellings which he first considers, *Common Vascular* or *Organized Sarcoma*. Under this title Mr. Abernethy includes all those tumours which appear to be composed of the gelatinous part of the blood, rendered more or less vascular by the growth of vessels

through it. The vessels which pervade this substance are, in different instances, either larger or smaller, and more or less numerous; being distributed in their usual arborescent manner, without any describable peculiarity of arrangement. Perhaps all the varieties of sarcomatous tumours are at first of this nature. The tumour under consideration is met with, not only in distinct tumours, but also in the testis, mamma, and absorbent glands. When a common vascular or organized sarcoma has attained a certain magnitude, the veins of the skin seem remarkably large, and their winding course under the integuments excites notice. This kind of sarcoma is not at all tender, so that it may be freely handled, and also electrified, without giving pain. The tumour sometimes grows to such a size that the skin bursts, the substance of the swelling sloughs out, and the disease is got rid of. However, this mode of cure is attended with such terrible local appearances, and so much fever, &c., that the removal of the disease with the knife is to be preferred. The enormous mass of 44½ pounds weight, involving the penis, testes, and scrotum, and lately removed by Mr. Liston, together with those organs (see *Edinb. Med. and Surg. Journ. No.* 77), was probably the kind of tumour which Mr. Abernethy would call a *common vascular sarcoma*. Other similar cases are noticed in another place. See *Scrotum*.

[*Delpech, Chirurgie Clinique, t.* 2, 4*to*. 1828. Professor Delpech gives an account of a patient aged 35, a native of Perpignan, whose scrotum was converted into an enormous mass weighing sixty French pounds, in which the penis, the spermatic cords, and the testicles were completely buried. Such a disease is much more frequently met with in hot than in temperate climates, as explained in the article *Scrotum* of this Dictionary, where a notice of some other remarkable instances of it will be found. The swelling described by Delpech was nearly pyriform, flattened transversely, divided at its lower front part into three principal lobes, and reached downwards below the calf of the leg. Behind, it formed a vast projection, and it was attached to the perinæum and hypogastric region by a neck or pedicle, that occupied the whole space comprised between the pubes, the two groins, and the anus. The circumference of the pedicle at its narrowest part was eighteen French inches. The patient could neither walk nor stand, without much difficulty. Although the organs of generation were buried in the manner thus specified, erections and seminal emissions occasionally took place. Some parts of the integuments were tuberculated; and in the anterior lobe of swelling, which was like a cauliflower excrescence, there was a transverse fissure, at the bottom of which was a deep sinus, running upwards and rather to the left: such was the state of the prepuce and passage through which the urine was discharged. For the particulars of the operation by which this enormous mass was removed, so as to leave two lateral flaps of sound skin for covering the testicles, I must refer to the above work. The extent of the wound may be conceived, when it is stated that the external pudendal artery, the artery of the septum scroti, the dorsal arteries of the penis, the transverse artery of the perinæum, the right and left arteries of the bulb, and several branches of the inferior hemorrhoidal, required ligatures, the ends of which M. Delpech cut off, in order that the quantity of extraneous substance in the wound might be lessened. Owing to the prodigious elongation of the spermatic cords, it was necessary to arrange them after the operation in a tortuous form, and some difficulty was experienced in fixing the testicles in their proper situation. The wound was completely cured in about two months; and the patient returned to Perpignan, where in the course of a few weeks he became indisposed and died. On opening the body, a very large abscess was detected in the liver. Must this be regarded as a consequence of the extensive wound inflicted in the operation, or as the result of the patient's excesses after the wound had healed? If the former view be adopted, it is another confirmation of the frequency of visceral inflammations and suppurations after severe local injuries or great operations; a subject on which much interesting matter may be collected in the *Memoirs of the Royal Academy of Surgery*, and in the papers of Messrs. Rose and Arnott in the *Medico-Chir. Trans. of London*.

With regard to the nature of the tumour, Delpech contends that it presented an example of true elephantiasis of the scrotum; a point on which many practitioners will disagree with him. The following circumstances relative to the structure and composition of the swelling are noticed. The skin of its anterior part was not less than three inches thick; and the inequalities observable upon every portion of it were here greatest. Notwithstanding the discolorations which the skin exhibited in places, where it was most deeply affected, the incisions in it bled very little; few vessels of considerable size were met with, and not a single varicose vein. The cellular tissue was manifestly every where distended, its lamellæ were lengthened, and included very large cells; most of them were semi-opaque and of a white pear colour, which change is ascribed by Desault to an inflammatory process that had thickened them. The areolæ of this tissue, besides being very dense, contained a serosity, a part of which flowed out in the operation, while the rest, in consequence of its greater consistence, did not escape from the cells, though they were opened. Both contained a large proportion of albumen, and were coagulated by heat or acids. Blood-vessels were seen ramifying in this tissue; but they were not numerous, and only of small size. The lymphatics were plainly discernible in great numbers and of considerable diameter. In front of the spermatic cord some fat was found, the only situation in which it presented itself; and here its accumulation made Delpech suspect, for a little while, that there was an omental hernia, with a very thin transparent sac. The cremaster seemed to have preserved the spermatic cord completely from the disease.

To the preceding history, Professor Delpech has annexed the case of what he terms an elephantiasis of the female sexual organs, removed by Dr. Talrich, of Perpignan. The disease, which originated just below the mons veneris, hung down as low as three inches above her knees, and, unless it was pushed towards the navel, rendered the evacuation of the urine difficult. It involved the labia, especially the right one; and the clitoris, which was considerably elongated by the weight of the swelling, was concealed under its root. I do not adopt the view taken by Delpech of the character of this swelling, which he contends was that of elephantiasis. Whoever will compare the description of the disease with the history of elephantiasis (see *Good's Study of Medicine, vol.* 3, *p.* 423, *ed.* 3), will see few points of resemblance between them.—*Pref.*]

[Tumours of a steatomatous nature often occur from the inner surface and from the outside of the uterus. Several remarkable specimens of this sort are in the collection of Professor Francis, of New-York. The particulars of two cases which fell under the observation of Dr. F., and occurred in the practice of Professor Mott, are given in Dr. Francis's third revised edition of Denman's Midwifery, New-York, 1829. In one of these cases, upon examination, the tumour was found to be of a fleshy nature, and of a fibrous vascular structure. It was almost wholly one solid mass. It grew by a peduncular attachment from the fundus of the womb. According to evidence taken at the time of examination, the tumour and its excrescences weighed rather more *than one hundred pounds*. The extent of the abdomen of the patient before the removal of the tumour measured four feet eight inches and a half. In the other instance, a number of tumours were found attached to the external surface of the uterus and its appendages. These tumours and the diseased uterus weighed thirty-two pounds four ounces. Other remarkable cases of this nature are stated in Francis's Denman. In one the external tumour was nearly the size of the head of a fœtus at seven months. In two other instances they were about two inches in circumference. These tumours occasionally create much constitutional uneasiness and false signs of pregnancy. But much depends upon the portion of the uterus from which they grow.—*Reese.*]

The second kind of sarcomatous tumour noticed in Mr. Abernethy's classification, is the *Adipose Sarcoma*. Every one at all in the habit of seeing surgical disease, must know that fatty tumours are exceedingly common. Mr. Abernethy believes that these swellings are formed in the same manner as others, viz. in the first instance they were coagulable lymph, rendered vascular by the growth of vessels into it, and that their future structure depended on the particular power and action of the vessels. According to Sir Astley Cooper,

"they are not composed of fatty matter only, but the adipose membrane is increased, and their structure is similar, only somewhat more compact, to that of the fatty membrane in other parts of the body."—(*Med. Chir. Trans. vol.* 11, *p.* 440.) This fact is very much against the doctrine which ascribes the origin of tumours to hydatids and their transformation. Adipose sarcomatous tumours always have a thin capsule, formed by the simple condensation of the surrounding cellular substance. It adheres very slightly to the swellings, and chiefly by means of vessels which pass through this membranous covering in order to enter the tumour. As Mr. Abernethy has accurately described, the vessels are so small, and the connexion so slight, that in removing the tumour no dissection is requisite, as the operator may easily put his fingers between the swelling and its capsule, so as to break the little vascular connexions, and entirely detach the disease. Some individuals seem to have a disposition to the formation of fatty tumours upon various parts of their bodies; a memorable example of which is recorded in the *Revue Médicale*. The patient was a young woman, aged 18, whose constitution was not in any way remarkable. Although very lean, and of the middle stature, she weighed 169 French pounds. Between her shoulders were two tumours, eight inches long and three broad. A third, of less size, was situated near the right armpit. A fourth arose from the inferior angle of the shoulder-blade, and was 15 inches long and six broad. A fifth, lower down, was six inches long and five broad. The sixth, which was larger than a man's head, was situated upon the right hip. The seventh, a small one, was below the right trochanter major. The eighth, a prodigious one, arose from the left hypochondrium, and hung down as low as the middle of the calf of the leg, being two feet long and three feet one inch in circumference at its base. All these tumours were of a fatty nature, soft, uneven, and quite unconnected with internal organs or the muscles.—(See *Quarterly Journ. of Foreign Medicine, vol.* 4, *p.* 618.)

The substance of adipose tumours is never furnished with very large blood-vessels, and the fear of hemorrhage, which frequently deters surgeons from operating, is quite unfounded. It is an undoubted fact, that there is no species of tumour that can be removed with so much celerity, with such apparent dexterity, or with such complete security against future consequences as those of an adipose nature. However, now and then, when the tumour has been sometimes in an inflammatory state, the capsule becomes thickened, and intimately adherent to the surface of the swelling, so that the separation of the disease is more difficult, and requires the knife to be more freely employed. The tumour also sometimes becomes, after inflammation, closely adherent to the contiguous parts. Adipose tumours often acquire an enormous magnitude. Indeed, there can be no doubt of the fact stated by Sir Astley Cooper, that they acquire a greater magnitude than any other swelling ever reaches. Mr. Abernethy relates an example of one, removed by Mr. Cline, which weighed between 14lbs. and 15lbs., and which I saw myself previously to the operation. Sir Astley Cooper also mentions the successful extirpation of several adipose tumours of immense size: one weighing 14lb. 10oz. removed by himself; and another weighing 22lbs. removed from a lady's thigh by Mr. Copeland. But a still more remarkable case is one, in which Sir Astley Cooper lately removed a fatty swelling, which weighed, independently of the blood in it, 37lbs. 10oz., and was situated on the abdomen of a man aged 57.—(See *Med. Chir. Trans. vol.* 11, *p.* 440.) In the case above quoted from the *Revue Médicale*, and recorded by M. Dagorn, of Morlaix, the largest of the swellings weighed, after its removal, 46 French pounds.—(See *Quarterly Journ. of Foreign Med. vol.* 4, *p.* 618.) Although it is true, that when adipose swellings attain an enormous bulk, the immense size of the wound requisite for their removal must be dangerous, and is a strong argument in favour of having recourse to the operation at an earlier period, yet it is equally true, that large fatty swellings may be taken out with a greater prospect of success than any other kind of tumour of equal size.

The next species of sarcoma, noticed in Mr. Abernethy's classification, is what he names *pancreatic*, from the resemblance of its structure to that of the pancreas. This kind of disease, it is remarked, is occasionally formed in the cellular substance; but more frequently in the female breast, on that side of the nipple which is next to the arm. When a pancreatic sarcoma is indolent, and increases slowly, the surrounding parts and the glands in the axilla are not affected. But some of these swellings deviate from their common character, and become of a very irritable nature, occasioning severe and lancinating pain, and producing an inflammatory state of the skin covering them, so that it becomes adherent to their surface. The absorbents leading to the axilla are also irritated, and the glands enlarged. Pancreatic sarcoma does not grow to a very large size; but when its progress is unrestrained, the pain attendant on the disease becomes lancinating, and so severe as to make the patients feverish, and lose their health and strength. Mr. Abernethy remarks, that when the axillary glands become affected, one generally swells at first, and is extremely tender and painful; but afterward the pain abates, and the part remains indurated. Another is then affected, and runs through the same course.

To another species of sarcoma, Mr. Abernethy applies the epithet *mastoid* or *mammary*, from the resemblance which this gentleman conceives its structure bears to that of the mammary gland. This kind of disease, Mr. Abernethy says, he has not often seen. In the example which he met with, the tumour was about as large as an orange, and situated on a woman's thigh. The swelling was removed by an operation; but the wound afterward degenerated into a malignant ulcer, attended with considerable induration of the surrounding parts, and the woman died of the disease in two months. Mr. Abernethy conceives, that the whole of the morbid part had been cut away, but that the contiguous parts had a disposition to disease, which was irritated by the operation, and that if the nature of the case could have been known beforehand, it would have been right to have made a freer removal of the substance surrounding the tumour.

Mr. Abernethy places the mastoid sarcoma between such sarcomatous swellings as are attended with no malignity, and the following ones which have this quality in a very destructive degree.

The *tuberculated* sarcoma is composed of a great many small, firm, roundish tumours of different sizes and colours, connected together by cellular substance. Some of the tubercles are as large as a pea; others equal a horsebean in size; most of them are of a brownish-red colour; but some are yellowish. Mr. Abernethy mentions his having seen this species of sarcoma chiefly in the lymphatic glands of the neck. The disease proceeds to ulceration; becomes a painful and incurable sore; and ultimately occasions death.

Another kind of sarcoma, mentioned in Mr. Abernethy's classification of tumours, is distinguished by the epithet *medullary*, from its having the appearance of the medullary matter of the brain. It appears to be an exceedingly malignant disease; communicates to the lymphatic glands a similar distemper; ulcerates and sloughs, and at last proves fatal. It is particularly apt to make its attack on the testis, and is treated of in other parts of this book.—(See *Fungus Hæmatodes*, and *Testicle, Diseases of.*)

Mr. Abernethy includes also in his classification *carcinomatous* sarcoma.—(See *Cancer.*)

I must refer to another article (*Mamma, Removal of*), for an account of the plan of removing sarcomatous tumours.

Besides many operations which have of late years been performed, and are remarkable on account of the great size of the swellings removed, others still more interesting claim attention, on account of the nature and situation of the parts extirpated. On the excision of the thyroid gland I need not here dwell, as it is elsewhere noticed (see *Thyroid Gland*); but I feel called upon to mention some other very bold operations, executed within the last few years. The first is that performed by Mr. Goodlad, of Bury, in Lancashire. The case was an immense tumour, situated on the left side of the face and neck, and the base of which was about twenty-eight inches in circumference. The disease extended from the external canthus of the eye above to within three quarters of an inch of the clavicle below, and some idea of the depth of its attachments may be conceived, when it is known that the whole parotid gland was involved in it. For the purpose of

obviating all danger of hemorrhage, Mr. Goodlad began with tying the carotid artery. The nature of the operation will be best understood by adverting to the appearances afterward presented by the wound. "The whole sterno-mastoid muscle was exposed, and its fibres dissected clean, except about half an inch from its insertion into the clavicle. The wound extended backwards from behind the mastoid process to the trachea anteriorly, but became narrower in the direction of the muscle at the lower part of the neck. The sub-maxillary gland was exposed, and about one-fifth of its substance not appearing healthy was removed. The digastric and the greater portion of the mylo-hyoideus were exposed. The ramus of the jaw was only covered by periosteum, except where covered by the masseter muscle, part of which not appearing healthy was dissected away. The whole of the condyloid process of that bone was laid bare in the same manner, and behind it the pterygoid muscles were also exposed. The membrane of the cheek was only covered by a cellular substance which did not appear healthy; but sufficient skin was saved to cover the zygoma. *The parotid gland was entirely removed.*" This enormous wound healed in ten weeks; but unfortunately the cure was not permanent; the disease returned, and fifteen months after the operation the poor woman died.—(See *Med. Chir. Trans. vol.* 7, *p.* 112, *&c. vol.* 8, *p.* 582.)

Respecting the foregoing severe operation, many surgeons may be inclined to doubt the propriety of tying the carotid artery as a preparatory step, and, indeed, it is positively condemned in an anonymous note attached to the above case; simple temporary pressure on the exposed vessel being represented as preferable. It appears to me, however, that Mr. Goodlad's method was justifiable, and on the whole the best, because the application of the ligature to the carotid not only removed the dangers of hemorrhage during the operation, but obviated them afterward, and no doubt lessened the necessity for a prodigious number of ligatures for vessels which would otherwise have poured out a profuse quantity of blood.

Nay, the hemorrhage is so profuse from the main branches of the external carotid, and mere pressure so uncertain of always commanding the flow of blood, that the patient may actually die from sudden loss of blood, as nearly happened in another very interesting case of removal of a large tumour involving also the parotid gland, and connected with the transverse process of the atlas, the basis of the skull, the meatus auditorius, mastoid process, and angle of the jaw. The operator, Mr. Carmichael, in order to complete the dissection, was obliged to divide the trunk of the facial artery: "Instantly (says he) an alarming gush of blood, which evidently came from a large vessel, followed the division; *and the danger appeared the more imminent as the pressure, which Mr. Todd applied with all the force he could exert upon the carotid trunk, was actually incapable of repressing the torrent.* There was not a moment to be lost. Mr. Colles plunged a dry sponge to the bottom of the wound, and firmly pressed on the bleeding vessel, while I made a horizontal section of the tumour, till I arrived at the cavities occupied by the sponge, with the view of exposing as quickly as possible the mouth of the bleeding vessel. This was accomplished in sufficient time to save the patient's life." Mr. Carmichael, at the conclusion of the history, remarks, that if he were called upon to perform such an operation again, *he would, in the first instance, pass a ligature under the carotid trunk, which might be* tightened or not as occasion should require. The case here spoken of had a successful termination. One remarkable consequence was a paralysis of one side of the face, brought on by the division of the trunk of the portio dura in the operation.—(See *Trans. of the King's and Queen's College of Physicians, vol.* 2, *p.* 101, *8vo. Dublin*, 1818.)

The next instance which I shall notice of the removal of an enormously enlarged parotid gland, is that recorded by Klein, the eminent operating surgeon at Stuttgard. The patient was a woman of seventy, and the swelling extended from the ear to the shoulder. In the operation, all the branches of the facial nerve were divided; a piece of the masseter was left hanging; the external carotid artery and par vagum were left quite bare; the dissected sterno-mastoid lay on one side; and the temporal, external maxillary and auricular arteries were of course divided along with several arteries of the neck; yet the largest of these being tied, the bleeding was very inconsiderable. The event was so successful, that at the beginning of the third week the wound was entirely healed.

The same distinguished surgeon also removed a fatty tumour, *extending from the buttock to the ham, and measuring three feet one inch in length, and two feet six inches in circumference.* Klein undertook its removal on the supposition that it was an encysted tumour lying above the fascia lata; but it turned out to be a steatoma coming from beneath it, and reaching to the thigh bone, and ... every direction among the muscles, nerves, and blood-vessels of the thigh. At length, partly with the fingers and partly with the knife, the fatty mass was separated from all its important connexions. Several vessels were tied, and among them the profunda femoris. However, not more than a pound of blood was lost. The tumour, after its removal, *weighed twenty-seven pounds and three-quarters.* The patient, a woman 44 years of age, went on very well for eight days; but on the ninth, she was constantly complaining of uneasiness in the foot of the affected limb; her pulse became weak and intermitting; and she sunk in the most unexpected manner.—(See *Journ. für Chirurgie Herausgegeben von D. L. Graefe und D. P. F. Walther, b.* 1, *p.* 106, *&c. 8vo. Berlin*, 1820; *or Quarterly Journal of Foreign Medicine, &c. vol.* 2, *p.* 373, *&c.*)

In the autumn of 1823, M. Beclard removed the whole of the parotid gland, which is described as being in a truly scirrhous state: the disease, however, returned, and the patient ultimately died of it. Two curved incisions were made so as completely to encircle the tumour. The portion of it situated on the masseter was first detached. Then an endeavour was made to separate the tumour from below upwards; but a continuation of it was found reaching a great depth backwards and under the pterygoideus internus. In order to avoid a hemorrhage, which it would have been difficult to stop in the operation, M. Beclard now determined to cut into the substance of the swelling, at the point where the deep production went off from it, and, dissecting from below upwards, he removed the mass; and, together with it, the lower half of the cartilage of the meatus auditorius externus, which participated in the disease. Numerous arteries being now tied, Beclard proceeded to the extirpation of the remainder of the tumour. A part of the front and inner surface of the mastoid muscle found diseased was cut away. Nearly the whole of the elongation behind the jaw had been cautiously dissected out, when a large jet of arterial blood indicated that either the external carotid or one of its branches close to its origin was divided. M. Beclard placed his left fore-finger on the point from which the blood issued, and a double ligature was applied, one portion of it above, the other below, the lateral opening in the carotid. The artery was now held forwards and a little raised, while the rest of the parotid was dissected out. Only one small continuation of the tumour, situated just in front of the cervical vertebræ, was left, on account of its nearness to the internal jugular vein; and it was tied. In the wound, the masseter was seen cleanly dissected. The branches of the seventh pair of nerves had been removed with the tumour; the labial artery, denuded but not wounded, was seen pulsating in front of the lower part of the masseter. The posterior part of the wound exhibited the mastoid process and the sterno-cleido-mastoid muscle. Internally, the styloid process, the external carotid tied with two ligatures, the stylo-hyoideus, digastricus, and, rather lower down, the small part of the tumour that was tied, formed the bottom of the wound which opened into the meatus auditorius externus. The following inferences are deduced from the case: First, The reality of scirrhus of the salivary glands is confirmed. Secondly, The possibility of removing the parotid demonstrated. Thirdly, Hemorrhage from a wound of the carotid in the operation may be stopped by ligature; but the attempt to remove by the first incisions that portion of the disease which is wedged behind the jaw, is dangerous, as opening the carotid might then prove fatal; whereas, if the largest portion of the tumour be first removed, and then the rest cautiously and slowly, the carotid, if now wounded, may be more easily secured, because the mass which lay over it has been taken

away. Fourthly, The erysipelas and delirium, by which the patient was afterward attacked, are common after operations on the face, and the return of cancerous disease but too frequent, even when completely extirpated. Fifthly, The paralysis of the muscles of the face which took place, is explained by the division of the branches of the seventh pair of nerves. —(See *Archives Gén. de Méd. Janvier*, 1824.)

A question may be entertained whether, in some morbid enlargements of the parotid gland, and parts extending deeply about the throat, it would not sometimes be better to be content with simply tying the carotid artery, and trying whether stopping this large supply of blood to the diseased parts would not be followed by an absorption of the tumour? Some facts appertaining to this question are noticed in the article *Aneurism*, where the aneurism by anastomosis falls under consideration. It will there be seen, that the result of this experiment is not sure of permanently repressing the growth of a tumour of this last kind, even when it has this effect at first. This uncertainty will, no doubt, incline many practitioners to prefer the bold method of extirpation. Yet others will perceive that such an operation, notwithstanding its success in a few examples, is dreadfully severe, and must of itself in the generality of cases have fatal consequences. They will also be encouraged, in any similar instance, to try the effect of the ligature, by the cure which Sir A. Cooper accomplished, of an enormous cutaneous enlargement of the lower extremity, by tying the artery in the groin. Indeed, I am sure, that as the improvements in modern surgery advance, the plan of curing tumours by cutting off their main supply of blood, will be much more extensively adopted than has hitherto been the case. In this way the surgeon may attempt the dispersion of many tumours which could not be meddled with in any other manner, and which, if left to themselves, must have a fatal termination. With respect to aneurism by anastomosis, the plan adopted by Mr. White, Mr. Lawrence, and Mr. Brodie, of extirpating it by a ligature applied round its base, is sometimes preferable to the use of the knife, which may bring on a perilous degree of hemorrhage.

Tumours, encysted. These, which are commonly named wens, consist of a cyst which is filled with different substances. When the contained matter is fatty, it is termed a *steatoma;* when somewhat like honey, *meliceris;* when like pap, *atheroma*. These are the three species into which writers usually divide encysted tumours. However, some of these swellings do not conform to either of the above distinctions, as their contents are subject to very great variety indeed, and are occasionally of an earthy, bony, or horny nature. Some encysted tumours of the latter description occasionally burst, and assume the appearance of horns, by the gradual projection of the matter secreted within their cysts.—(See *Sir Everard Home's Obs. on the Growth of Horny Excrescences, in Phil. Trans. for* 1701.) In the year 1824 I attended with Mr. Drew, of Gower-street, a medical gentleman, from whose hip I removed a swelling of this nature, which had become very troublesome in consequence of its pressure making the parts around its base inflame. It had been cut off many years ago by another surgeon, but grew again. At present (1829), there is no appearance of its reproduction, against which I guarded by carrying the incisions very deeply. I saw an excrescence of this kind removed some years ago from the scrotum of a man in St. Bartholomew's Hospital. Sir James Earle performed the operation, and, if I am not mistaken, the preparation of the disease is now in the museum of that institution. But still more remarkable specimens of such excrescences are preserved in the Anatomical Museum of St. Thomas's Hospital; one in particular, which resembles a ram's horn in shape, and was removed from a gardener's head at Kingston, by Dr. Roots. A farther account of the case is given in Rees's Cyclopædia, article *Horny Excrescence*.

I suppose every body in London has now seen in the British Museum the horn deposited there as a curiosity, and which, with another of the same size, grew upon the head of a human subject. What is equally curious, hairs are not unfrequently found growing in the cavities of encysted tumours (*Delpech, Précis des Mal. Chir. t.* 3, *p.* 412); and even teeth, more or less perfectly formed, have been strangely met with in the same situations. An interesting specimen of the latter occurrence, in a double encysted tumour in the orbit, was published some time ago by my friend Mr. Barnes, of Exeter.—(See *Med. Chir. Trans. vol.* 4, *p.* 316.)

It is observed by Sir Astley Cooper, that it is when encysted tumours are situated upon the temple and near the eyebrows and other hairy parts, that they sometimes contain hairs: these "have no bulbs nor canal, and differ therefore from those which are produced on surfaces of the body which naturally form hair." In sheep, the cysts sometimes contain wool.—(*Surgical Essays, part* 2, *p.* 233.) The manner in which these horny excrescences are produced is stated to be as follows: "The horn begins to grow from the open surface of the cyst; at first it is soft, but soon acquires considerable hardness; at first it is pliant, but after a few weeks it assumes the character of horn."—(*Vol. cit, p.* 235; see also *Home, in Phil. Trans. for* 1791.)

Encysted tumours are generally of a roundish shape, and are more elastic than fleshy swellings. However, the latter circumstance depends very much upon the nature of their contents and the thickness of their cysts. As far as my observation extends, encysted tumours form more frequently on the head than any other part; but they are very frequently met with in all situations under the integuments, and sometimes in deeper places. Encysted tumours are also very often seen on the eyelids.

According to Sir Astley Cooper, they are in general nearly globular, and when seated on the head feel very firm, but upon the face they are attended with a fluctuation more or less obscure. The skin covering them is generally uninflamed; but it is now and then streaked with blood-vessels which are larger than those of the surrounding integuments. "In the centre of the tumour on the skin, it often happens that in its early state, a black or dark-coloured spot may be seen, which sometimes continues through the whole course of the disease. In general, they are unattended with pain, are never in themselves dangerous, and only require removal from the parts in which they occur, and the unseemly appearance they produce. They move readily within the cellular membrane if they are free from inflammation, but the skin in general does not easily move over them."—(*Surgical Essays, part* 2, *p.* 230.) The greatest number of encysted tumours which this experienced surgeon has met with in the same individual was sixteen, situated upon the head; and he has seen nine in another patient, as many as which number on one person I have seen myself. Four, five, and six, as Sir Astley remarks, are not uncommon. The largest which he has ever seen was equal in size to an ordinary cocoa-nut, and grew upon the head; but in general they are not more than one or two inches in diameter. He considers them in some degree hereditary, as he has often heard a patient observe, "I have several swellings upon my head, and my father (or my mother) had several." They also frequently occur in several of the same family.—(*P.* 231.)

According to Sir Astley Cooper, when encysted tumours are dissected, some part of their surface is found firmly adhering to the skin, while other parts are connected to it merely by the cellular membrane. The cyst itself is imbedded more or less deeply in the cellular membrane, and its thickness is different in different parts of the body. On the face or near the outer canthus the cyst is very thin; but on the back it is much thicker, and on the head it is so thick and firm that it retains its form after the discharge of its contents, and is so elastic that after being compressed it readily expands again to its former size. Within the cyst, Sir Astley Cooper remarks, there is a lining of cuticle which adheres to its interior, and several desquamations of the same substance are formed within the first lining. If the vessels of the cyst are injected, they are found to be numerous, but of small size. The cysts are occasionally met with in an ossified state.—(*Surgical Essays, part* 2, *p.* 232, 233.) It is the opinion of Sir Astley Cooper, that encysted tumours arise from the enlargement of the follicles or glandular pores, in consequence of the obstruction of their orifice.—(*P.* 236.) If this sentiment were correct, the fact would furnish another consideration against the view taken of the formation of tumours by Dr. Baron. There are some reasons, however, which render the adoption of Sir Astley's explanation difficult; for if encysted tumours were only

enlarged follicles, they would not be found so far from the skin as they frequently are; as, for instance, within the orbit, between the peritoneum and abdominal muscles, and in other situations yet farther from the surface of the body; and the collections of sebaceous matter which are so often noticed, as this gentleman observes, in the follicles of the skin of the nose, and may be pressed from them in the form of worms, would, if the cause assigned were true, make encysted swellings on the nose itself exceedingly common; yet this part is not so often the seat of such tumours as other parts of the face. As far also as my observations extend, pressure cannot be said to have any share in giving rise to the formation of encysted tumours, because I have seen them chiefly in situations where this kind of cause could not be suspected; as, for instance, on the face and about the vertex, and not particularly round that part of the head which is compressed by the hat. If also encysted swellings were owing to obstruction of the cutaneous pores with sebaceous matter, I apprehend few persons would escape the disease. The cure in the early stage would also be as easily effected by the timely removal of the alleged obstruction, as the cure of the little tender points on the nose, really caused by the lodgement of the sebaceous matter in the cutaneous pores. This does not appear to me to be consonant to general experience. How the formation of steatomatous encysted swellings is to be thus accounted for, I cannot at all conceive. And, lastly, it is to be noticed, that the little swellings on the nose, arising in the way described, are, when they occur, frequently attended with soreness, from which true encysted tumours, at least in the early stage, are completely free. These and other reflections lead me to believe, that the origin of encysted swellings cannot be satisfactorily explained upon the principles suggested by the above distinguished practitioner. At the same time I ought to thank him for his kindness in showing me two cases, in which the fact of there being an opening in the skin, communicating with the cavity of the swelling, and giving occasional exit to its contents, was completely manifest; but whether such opening actually were, or ever had been, the orifice of a sebaceous gland of the skin, is a point which I cannot undertake to determine. However, as all Sir A. Cooper's opinions on surgical questions are deservedly valuable, I subjoin the advice which he has given, founded upon the preceding doctrine. If the follicle can be seen only as a black spot filled with hardened sebaceous matter, he recommends a probe to be passed into it, and the sebaceous matter to be pressed out of the tumour, which is done with little inconvenience. But if the contents cannot be pressed out without such violence as would create inflammation, he says that the best plan is to make the opening larger. Other surgeons have tried to cure encysted tumours by pricking them with needles and squeezing out their contents; by opening them more freely, and filling them with lint or charpie (*Delpech, Clinique de Chirurgie; t.* 2, 1828); or by applying stimulating and discutient applications to them. However, some of these plans mostly fail, and the others sometimes convert the case into a terrible disease, in which a frightful fungus shoots out from the inside of the cyst, attended with immense pain and irritation, and often proving fatal.—(See *Abernethy's Surgical Observations*, 1804, *p.* 94.)

Similar dangerous fungous diseases may also arise, whenever the surgeon, in cutting out encysted tumours, leaves any part of the cyst behind.

The most advisable method, I believe, is, to have recourse to the knife, before an encysted tumour has attained any considerable size. However, if it is large at the time of the operation being done, a portion of the skin must be taken away with the swelling, in the manner described in the article *Mamma, Removal of*. The chief piece of dexterity in the operation consists in detaching all the outside of the cyst from its surrounding connexions without wounding it. Thus the operator takes the part out in an entire state, and is sure that none of the cyst remains behind. When the cyst is opened, some of the contents escape, it collapses, and the dissection is rendered more tedious and difficult.

Such is the common opinion, which has always appeared to me correct. However, Sir Astley Cooper states, that the best manner of doing the operation is, to make an incision into the swelling, and then to press the sides of the skin together, by which means the cyst may be easily detached and removed. If the attempt be made to extract the tumour whole, "the dissection is most tedious, and, before it is completed, the cyst is either cut or burst. So many incisions, and so much pain, may be readily prevented by opening it freely by one incision, raising its edge between the forceps," and dissecting it from its adhesions to the surrounding membrane.—(*Surgical Essays, part* 2, *p.* 240.) When the swelling is in the scalp, Sir Astley directs an incision to be made through its centre, from one side to the other, when its contents, which in this situation are very solid, are immediately discharged in a mass of the same shape as the tumour. The cyst being raised with a tenaculum, may then be easily separated.

When the foregoing difficulties are likely to be encountered, a late writer suggests the plan of first opening the cyst, washing out its contents, and then injecting into it a thin mixture of sulphate of lime, which will immediately harden, and facilitate the excision of the cyst.—(*M'Ghie, in Ed. Med. Journ. No.* 76.) This proposal, though ingenious, is perhaps not likely to be adopted, because the operation, which is generally easy enough without it, would thus be rendered long and complex.

With respect to encysted tumours of the eyelids, the atheroma and meliceris are said by Beer to form only upon the upper eyelid, on the side towards the temple, while he has always found the steatoma to be seated either in the vicinity of one of the eyelids, or sometimes over the lachrymal sac. The atheroma and meliceris, he says, usually lie in the loose cellular substance directly under the skin of the eyelid, though sometimes more deeply under the orbicularis muscle, or even quite underneath the levator palpebræ superioris, upon the convex surface of the tarsal cartilage, to which the swelling is then generally so firmly adherent, that it is impossible to remove this part of the cyst. Encysted tumours of the upper eyelid are commonly so moveable, that they can be pushed above the superciliary ridge of the os frontis; which is regarded by Beer as a very favourable circumstance in the operation. Though the atheroma and meliceris of the upper eyelid occasionally become as large as a pigeon's egg, Beer has never known a steatoma, in the vicinity of the eyelids, exceed the size of a hazel-nut. Encysted tumours of the upper eyelid itself sometimes appear moveable, though they may be at the same time closely adherent to the cartilage. Hence, Beer recommends moving the tumour about for a few days before the operation, and trying to push it above the superciliary ridge; and, if this cannot be done, the circumstance will prove, that the swelling is connected with the cartilage, or at least is under the orbicular muscle, and the mode of operating regulated accordingly. With the yellow pappy substance, found in the cysts of atheromatous tumours of the eyelids, fine short hairs, scarcely one line in length, are frequently blended. Sometimes, as Beer remarks, the whole inside of the cyst is covered with these little short hairs, which may all be washed out, and are destitute of bulbs: a fact also noticed by Sir Astley Cooper. It merits attention, however, that in tumours of the meliceris kind, formed upon the eyelid, Beer never met with hairs.—(*Lehre von den Augenkr. b.* 2, *p.* 607—609.) He remarks, that when encysted swellings of the eyelid are let alone, he has never known them produce any injury to the eye itself, except in the hindrance to the opening of it, when they are large. On the other hand, if they be unskilfully removed, or rashly attacked with caustic, various ill consequences may ensue; as, for instance, fistulæ of the lachrymal gland, entropium from a shrinking of the tarsal cartilage, ectropium from destruction of the skin, and the hare-eye from an actual shortening of the upper eyelid. In consequence of the inflammation caused by escharotics, Beer has more than once found the integuments so adherent to the tumour, that in the operation the removal of a considerable piece of them was unavoidable. But, says he, when swellings of this nature are properly treated in good time, they may be removed without leaving any vestige behind, excepting a trivial scar. Professor Beer joins all the best modern surgeons in considering the entire removal of the sac, and the reunion of the wound by the first intention, as the safest and most

effectual method of curing encysted tumours of the eyelids. He admits, however, that the hinder portion of the cysts of some swellings of this nature upon the upper eyelid cannot be dissected out, because it may be so closely adherent to the cartilage, that its excision would injure the latter part too much, and produce either an incurable entropium, or an irremediable shortening of the eyelid. But steatomatous tumours near the eyelids may almost always be completely dissected out, the only exceptions being cases in which the swellings happen to be situated between the lachrymal sac and the orbicular muscle, and so intimately connected with the first of these parts, that the back portion of the cyst could not be cut away without permanently destroying the functions of the excreting parts of the lachrymal organs. However, when the swelling is not too strongly attached to the cartilage of the eyelid, Beer sanctions the removal of the whole of the cyst. He particularly insists upon the utility of moving the tumour a good deal about daily, for a few days before the operation, so as to loosen its connexions, and enable the surgeon to push it over the edge of the orbit, where it may be steadily fixed during its removal. —(*B.* 2, *p.* 612.) Excepting a few instances in which the skin was diseased, and firmly adherent to the cyst, Beer has never found it necessary, in the excision of encysted swellings of the eyelids, to remove any portion of the integuments; and he has cut away some tumours of this kind which were as large as a pigeon's or hen's egg. The incision through the skin, he says, should be longer than the tumour, so as to facilitate the extraction of the distended cyst.—(*B.* 2, *p.* 613.) When it is not advisable, for reasons above stated, to attempt to dissect out every particle of the cyst, Beer fills the cavity with lint, lets the wound suppurate, and, if this plan is not sufficient, he applies stimulants and caustic. It is noticed by Sir Astley Cooper, that encysted tumours at the outer canthus are often difficult of removal, on account of their extending into the orbit, and being adherent to the periosteum.—(*Surgical Essays, part* 2, *p.* 241.) Professor Scarpa has strongly recommended making the incision for the extraction of encysted swellings of the palpebræ on the inside of these parts. But, as Mr. Travers correctly remarks, the swellings are often situated superficially, and loosely connected with the tarsus; in which case, the operation should be done on the outside of the eyelid. The latter writer admits, however, that the cyst is often formed between the cartilage and the ligamentary membrane which covers it; and, in his opinion, it is only when an intricate adhesion subsists, and the appearance of a white circumscribed indentation is seen upon the everted tarsus, that the excision should be performed on the inside of the eyelid by dividing the cartilage.—(*Synopsis of the Diseases of the Eye, p.* 357.)

I shall conclude the subject of tumours with a few observations, delivered by Sir Astley Cooper and Professor Langenbeck. "The removal of encysted tumours (the first gentleman observes) is not entirely unattended with danger. I have seen three instances of severe erysipelatous inflammation succeed the operation of removing these swellings upon the head, and I believe it is owing to the tendon of the occipito-frontalis being wounded in the attempt to dissect them out whole."—(*Surgical Essays, part* 2, *p.* 241.)

In the extirpation of tumours about the neck, Langenbeck adopts the following rules: he makes a free division of the integuments, and dissects the muscles from the tumour which lie over it, but he avoids cutting through or injuring them: in this manner the swelling is rendered more moveable. By the situation of the muscles, he is then enabled to know the place of the chief blood-vessels; and, on this account, he particularly advises young surgeons to study myology with the greatest care. As Langenbeck remarks, it is indeed an important advantage, after a muscle is exposed, to know what vessels lie at its edges or underneath it. Thus, the sartorius is a sure guide to the crural artery, and the sterno-cleido-mastoideus to the carotid. A surgeon who knows correctly the anatomy of the parts will not be in danger of wounding unintentionally any large vessel. When the surface of the tumour has been cleared, but the base of it is yet firmly attached, Langenbeck commences the separation on the side which presents the least risk, that is where the least considerable blood-vessels are, and thence he proceeds by degrees towards the most hazardous side. In favour of this method, he offers the following considerations: if, by chance, an artery requiring a ligature should be cut, it can now be more easily secured, as the base of the tumour is already partly detached. The loosened swelling may also be drawn away from the large vessels with the hand or a tenaculum. Langenbeck never introduces the knife deeply when there are large blood-vessels there, but pulls the swelling outwards, and then divides the cellular substance thus stretched, which is situated upon the already exposed portion of the tumour. In this manner the swelling can always be drawn more and more away from the vessels, until at last there is no danger of wounding them. By attending to these principles, Langenbeck has succeeded in removing many very large tumours from the neck, where nearly all the muscles of that part were exposed by the dissection, and the carotid denuded. After one of these operations, not only the styloid process could be felt, but all the muscles originating from it could be distinctly seen.—(*Bibl. für die Chir. b.* 2, *p.* 312, *&c.* 12*mo. [Delpech has published, in the second volume of his *Chirurgie Clinique*, numerous cases of what the French call *cysts* (kystes), including, besides the ordinary encysted tumours of surgical writers, hydrocele, dropsy of the ovary, and certain collections of fluid, that would rather be classed by us with chronic or scrofulous abscesses. His first case, which consisted of a very large collection of imperfect matter and serous fluid, in the neck of a female, was one of this latter description, though, on account of the matter being contained in a pouch, the disease might certainly be called a cyst, or an encysted swelling. His treatment of this first form of cysts, the *séro-mucous*, as he names them, consists in opening them, discharging their contents, and then producing inflammation and suppuration of their whole extent by filling them with charpie, and persisting in this method until their cavities are obliterated. An enormous encysted tumour, which had been increasing in the orbit for twenty-one years, attended with displacement of the eye, immense enlargement of the orbit, and other deformity, was successfully treated on the same principle. Also, in another patient, a smaller cyst, containing three ounces of yellowish limpid fluid, and causing a protrusion of the eye, was cured in a similar way. According to Delpech, the treatment of encysted swellings should depend upon the diversified texture of their cysts. Some cysts are thin and transparent, often contain hairs, inserted into them

obliquely, and hold a limpid, slightly viscid fluid. These Delpech calls *serous* or *sero-mucous cysts;* and he says that they admit of cure by the foregoing plan. Another kind of cyst has more consistence, is thicker, rather opaque, and composed of two layers; the inner one fleecy, the outer partaking of the appearances of horny tissues. Hairs are frequently inserted into its cavity obliquely, and the matter which it contains is a white or yellowish sort of pulp, compared to pap, honey, or suet. Hence the terms *atheroma*, *meliceris*, and *steatoma*. Such cysts Delpech would name *horny*. A third class of cysts presents a lamellated structure, or a series of strata, with a cavity of moderate size. The external strata have a fibrous appearance; the middle and internal have less and less consistence, and exhibit the characters of albumen, or what is called coagulable lymph, or pseudo-membranes. To Delpech it is clear, that the whole is derived from the same origin, and that this substance, as seen in the different strata, has various degrees of organization. Such cysts he calls *albuminous;* they generally contain a moderate quantity of gelatinous matter. Other cysts exhibit an assemblage of cellular and fibrous tissues; they are disposed to acquire much greater dimensions than the rest, and their contents are subject to greater variety. For the most part, however, the fluid in them is a mixture of serum and albumen; sometimes it is brownish, and more or less viscid; and, in a few rare instances, it is gelatinous, or composed of albumen nearly pure, either liquid or concrete. Frequently, in the substance of their parietes, layers of osseous matter are noticed, and sometimes calcareous deposites in their cavity. Delpech calls these cysts *fibrous*. They are mostly developed in the ovaries, where they frequently grow to such a size, that they fill the whole of the abdomen, and, according to his statement, are occasionally combined with carcinomatous disease.

The *horny cysts* do not admit, as the sero-mucous ones do, of having their cavity gradually obliterated by the effect of inflammation. When treated on this principle, they sometimes assume the appearances of cancer. Such appearances Delpech has found to be constantly rendered worse by the cautery; but, if extirpated or amputated, he never knew the disease to be followed, either directly or remotely, by any carcinomatous mischief in other parts. This seems to the learned professor a satisfactory proof, that the fungous painful disease, into which a cyst, when improperly irritated, is sometimes converted, is not true carcinoma; a point which, I believe, has long been admitted by every judicious surgeon in this country. In operating upon horny cysts, I observe that Delpech, like Sir Astley Cooper, lays them open, squeezes out their contents, and then takes hold of their inside with a pair of forceps, and extracts them; their loose connexion with the surrounding cellular substance rendering this process easy. As Delpech had only had opportunities of seeing *albuminous cysts* in the practice of others, who adopted the plan of extirpating them, he refrains from entering into the consideration of their treatment. However, of ovarial cysts, which are most commonly, but not always, of the kind he calls fibrous, he offers many cases accompanied by observations. In one of his dissections, a sero-mucous and a horny cyst were both found connected with the ovary: a case which he deems exceedingly rare. He affirms, that the cure of an ovarial cyst has never been observed, whether as the work of nature or art; and nothing can be cited, that would justify any comparison with the spontaneous or artificial terminations of the sero-mucous and horny cysts. From the cases and dissections of ovarial cysts which he records, he deduces, among other inferences, the following: 1. They are the product of a particular and accidental organization, and by no means of the gradual dilatation of the natural vesicles of the ovary. 2. Observation has not yet sufficiently proved, whether, under favourable circumstances, this or any other kind of cyst of the ovary is ever formed alone, unaccompanied by any other change of this organ. 3. Most frequently, cancer is at the same time developed, masses of this nature existing either upon or between the layers of the cyst. Here I must observe, that the sarcomatous substances so commonly attending ovarial cysts are not usually regarded by British surgeons as truly carcinomatous; nor can I discover, that Delpech brings any proof of the correctness of this part of his observations. The question is also a material one, inasmuch as it has great influence on the practical point, whether paracentesis and other active measures should be undertaken or not? 4. The statement, that there are always several cysts, does not agree with Dr. Baillie's account of the whole ovary being sometimes converted into a capsule.—(*Works, by Wardrop, vol. 2, p.* 315.) In their structure they are alike, though their parietes may differ in thickness; but the nature of the matter which one cyst contains may be very different from what is included in another, independently of the effect of any incidental inflammation. This remark coincides with what Dr. Baillie has said on the same point. 5. Only one cyst attains a vast magnitude, so as to fill the cavity of the abdomen, and though the others increase, they do not exceed a middling size. 6. The parietes of the cysts do not become thin in proportion to their distention; but, on the contrary, grow thicker. 7. The cysts communicate with one another only accidentally. This disposition is sometimes remarked after paracentesis, or some other surgical proceeding calculated to produce an inflammation of some duration in the morbid mass; but Delpech thinks that we have no ground for presuming that it ever happens spontaneously, and from the mere effect of distention or ulceration; an opinion which, I conceive, requires farther confirmation. 8. For the most part, the origin of the disease is quite clandestine; the swelling being the only thing at first taken notice of. If pains are sometimes experienced in the situation of the ovary, or in that of the uterus, it is not till the tumour has made a considerable progress and has been of long standing. Such pains are always exceedingly vague, and only manifested by some sympathetic ailment; and it may be doubted whether they may not rather depend upon distention than organic disease. At all events, nothing justifies the suspicion of their dependence upon inflammation. 9. Inflammation sometimes originates spontaneously in an ovary containing cysts; but more frequently, its cause is active injudicious treatment. Hence arise particular symptoms, readily distinguished from such as belong to the organic disease. Dissections evince that the inflammation leads to a deposite of different quantities of concrete albuminous matter or pus in only some of the cysts. And Delpech believes that the inflammatory process does not readily establish itself; nor easily spread to the whole mass of an ovary in this state. 10. An ovarial cyst may enlarge in such a degree that the whole abdomen is filled by it. When the surrounding peritoneum inflames, the cyst may become adherent to all the viscera and to the parietes of the belly. Under these circumstances, its strength is augmented by the support of all the circumjacent parts; and if inflammation be kept off, and the accompanying scirrhous substances should not increase, the disease may remain stationary for many years. 11. The cyst may burst and some of its contents pass into the peritoneum, where a dangerous inflammation may be the consequence. Several examples of this occurrence are recorded by Delpech. 12. The accident can hardly be recognised with certainty by the symptoms; but it is to be apprehended, when the tumour augments rapidly, attended with acute fixed pain. 13. Here the proper treatment will depend upon the consequences of the rupture. When absorption of the extravasated fluid ensues, the surgeon will be prudent not to interfere much; but if this desirable event should not take place, Delpech recommends paracentesis to be performed on the opposite side. 14. As no treatment is known that will cure the organic disease of the ovary, and active medicines create serious irritation in the abdominal viscera, which Delpech describes as peculiarly irritable in this disorder, he lays it down as a fundamental rule in practice, that they ought not to be employed. 15. As puncturing the tumour when a fluctuation is evident creates a risk of bringing on peritonitis, or such hemorrhage as cannot be commanded, the operation should never be done for the first time, unless the cyst be about to give way. Delpech advises the puncture to be generally made at the side of the hypogastrium, corresponding to the diseased ovary. If, however, the fluctuation should be plain at the bottom of the vagina, and the tumour should not quit this place in the different attitudes of the patient, he considers that this is the most advantageous situation for the puncture. If the cyst should form a projection at the

navel as sometimes happens, this part should be selected. 16. A puncture may be undertaken with more confidence, when one has been previously made *without ill consequences*, provided care be taken to make the opening precisely in the situation of the former. 17. In these last cases, if the patient's strength be not too much reduced, Delpech sanctions the attempt to establish an artificial fistula by leaving in the puncture an elastic gum catheter; but if inflammation come on, the scheme is to be renounced. 18. Le Dran's operation of making a free incision into the cyst (See *Paracentesis*) is condemned, as likely to excite peritonitis, and aggravate what Delpech calls (as I think without foundation) the *cancerous* masses around the cyst. These consequences he thinks the more likely to follow, as experience proves, that such treatment produces an extensive mortification of the cyst. 19. An inflammation of the large cavity of the cyst, he conceives, is sometimes the cause of death, even without peritonitis. 20. Every thing that is known respecting ovarial cysts, proves to Delpech, that they are incapable of undergoing the kind of diminution which takes place in the sero-mucous ones; that when punctured and kept open, whether they inflame or not, they subside, and are thrown into folds, but still retain their cavity, and the property of secreting the same fluid as heretofore; that when the puncture closes, the cyst fills and expands again, sometimes with an unusual degree of pain in consequence of the adhesions formed in its empty state; that the punctured part then generally re-opens spontaneously; that the inflammation caused by opening the cyst with a bistoury is not more effectual in bringing on adhesive inflammation, than what follows either a simple puncture, or this plan succeeded by that of keeping up a fistulous aperture; that the practice of an incision, and its consequent perils, have most frequently only terminated in the formation of such an opening; that, in a few rare examples, in which the operation produced a complete obliteration of the cavity, the whole cyst was destroyed by gangrene. 21. The project of treating an ovarial cyst like a hydrocele is strongly disapproved of by Delpech, with whose opinion the observation of some attempts of this kind leads me fully to coincide.—(See *Paracentesis.*)

It appears to me, that notwithstanding the possibility of the accident, Delpech overrates the danger of internal hemorrhage from puncturing an ovarial cyst; and that he ought to have admitted the severe indisposition, the oppression of breathing, the retention of urine, and other urgent symptoms, often produced by the great pressure of the swelling, as circumstances rendering the operation indispensable for the present relief of the patient. The reader may usefully compare what has been here said with that part of the article *Paracentesis* which treats of ovarial dropsy.—*Pref.*]

[*An Account of some of the most important Diseases peculiar to Women*, 8vo. *Lond.* 1829. *By Robert Gooch, M. D.* In the fourth chapter of this valuable and practical work, the reader will find many interesting remarks on polypi of the uterus. The disease, he observes, is commonly mistaken for a long time for profuse menstruation; the patient, instead of menstruating regularly and moderately, has frequent and profuse hemorrhages from the uterus, and in the intervals a pale discharge. These gradually drain her circulation and injure her health, until she acquires the deadly paleness, and suffers the complaints, which are the ordinary effects of deficiency of blood. The absence of pain from the uterus or pelvis (for there is often none, and never that degree which attends the malignant diseases of this organ) prevents all suspicion that the hemorrhages depend on a disease of structure. Tonics and astringents are given in various forms; one practitioner is consulted after another; till, at length, the uterus is examined, and a polypus is discovered. In ascertaining the nature of the tumour, for the purpose of determining the propriety of removing it by an operation, Dr. Gooch considers the mode of its attachment as one of the chief guides; and, in this respect, what is true of polypus of the fundus is not so of polypus of the neck and orifice. In polypus of the fundus, the stalk is completely encircled by the neck of the uterus, and if the finger can be introduced into the orifice, it passes easily round between the stalk and the encircling neck. In polypus of the neck, the finger cannot be passed quite round the stalk: it may be passed partly round it; but it is stopped when it comes to that point at which it is attached to the neck. In polypus of the edge of the orifice, the stalk does not enter the orifice, but grows from the edge of it, and is not encircled by it. With respect to the structure of polypi, Dr. Gooch describes them, when cut open, as presenting a hard whitish substance intersected by membranous partitions; but, he adds, that they are sometimes of a much softer and looser consistence, and sometimes have considerable cavities in them. Their external covering is the mucous membrane of the uterus. Their size differs greatly in different cases. Dr. Gooch has removed several which were as large as the head of a new-born child. They are commonly of a much more moderate size; and he has known several cases in which frequent hemorrhages were occasioned by a polypus not larger than a filbert, attached just within the cavity of the neck of the uterus.

According to Dr. Gooch, a polypus of the fundus uteri sometimes passes through the orifice of the womb gradually and insensibly; sometimes suddenly, during the action of the bowels. He has known several instances, in which patients, after this action, were suddenly seized with retention of urine, and, on examination, a polypus was found in the vagina, compressing the urethra.

Another valuable observation made by Dr. Gooch is, that the bleeding comes from the tumour and not from the uterus itself; for "as soon as a ligature is applied, and tightened round the stalk, the hemorrhage from that time ceases, although it may be several days before the tumour comes away." He notices the opinion of M. Levret, that a polypus does not bleed while it remains within the uterus; but that after its expulsion into the vagina, the orifice of the uterus, by compressing its stalk, impedes the return of blood in its veins, which consequently burst and bleed profusely. The incorrectness of the first part of this statement he convincingly proves.

The tumours which are likely to be mistaken for polypi, are, 1st, the prolapsed uterus; 2dly, the inverted uterus; 3dly, malignant excrescences from the uterus. In a prolapsus, besides the distinctions usually noticed, Dr. Gooch adverts to the sensibility of the tumour as a criterion; a polypus being insensible, so that if pricked or scratched the patient does not feel it. With regard to inversion, when this is only partial, that is when only the fundus descends through the os tincæ into the vagina, and the patient has survived for many months, the tumour feels exactly like a polypus of the fundus. Here the distinguishing circumstances are its sensibility, and the time of its first appearance, which must have been immediately after delivery.

When there is doubt, whether the case is a polypus or a malignant excrescence, Dr. Gooch recommends the application of a ligature, if the swelling has a stalk which can be tied without any danger of including the neck or fundus of the uterus. According to his experience, the plan succeeds in an immense proportion of cases; and he has known it succeed in several, attended with a cauliflower roughness of the tumour. Even if the excrescence should return, the patient, he says, would not be worse off than she was previously.

This excellent physician strongly enjoins the constant observance of the practical rule commended by all men of good judgment and experience; namely, that whenever hemorrhages from the uterus resist the ordinary means, the nature of the case should be certified by manual examination.

For the extirpation of polypi, Dr. Gooch prefers two tubes, resembling those described and engraved in Richter's *Elements of Surgery*, and my *First Lines of the Practice of Surgery*; but they are straight instead of being curved, which last shape he finds very inconvenient. The danger of including the uterus in the ligature, he thinks, may always be avoided by the following rules. 1. Instead of aiming at passing the ligature as high as possible on the stalk, it is to be passed as low as possible, care being taken, however, to pass it over the body of the tumour. He knows by experience, that the portion of stalk left above the ligature will not grow again, but, like the remnant of umbilical cord, dies and falls away. 2. When the stalk grows from the cervix, the os uteri, if it can be felt, will best denote where the neck ends and the stalk begins. The

ligature ought to be applied a little below the orifice; but if this cannot be felt, the next best guide is the ordinary length of the projecting part of the neck, that is, about two-thirds of an inch. When the polypus is very large, and the vagina closely contracted, it is difficult, or impossible, to reach the stalk and the cervix so as to make an accurate measurement, and the first rule only is practicable. 3. To attend to the sensations of the patient when the ligature is tightened; for if it give much pain, a part of the uterus is most probably included.

When a polypus grows from the neck or lip of the uterus, it sometimes occasions merely an obstinate and profuse leucorrhœa. A case is related by Dr. Gooch exemplifying this fact, and the great liability of diseases of the uterus to be mistaken, unless a manual examination be instituted.

Women who have a polypus, especially one growing from the neck or lip of the uterus, sometimes become pregnant. Of this Dr. Gooch has known two instances. In one, the tumour was discovered in the fifth month of pregnancy, and was removed by ligature. The pregnancy went on to the ninth month, when the patient was safely delivered. In the other case it was not discovered till the commencement of labour, and it occasioned death a few hours after delivery.

After relating many important cases, and adding some valuable reflections on the excrescences likely to be mistaken for polypi, Dr. Gooch concludes with this remark, well deserving of recollection, namely, that "where we see one case of cauliflower excrescence, we see ten or even twenty of common polypus, and fifty of carcinoma or malignant ulcer of the uterus." Every medical man should study Dr. Gooch's work most attentively, for it abounds in sterling practical information.—*Pref.*]

TYMPANUM. For an account of its diseases, see *Ear*.

U

ULCERATION is the process by which sores or ulcers are produced in animal bodies. In this operation, the lymphatics appear to be at least as active as the blood-vessels. An ulcer is a chasm, formed on the surface of the body by the removal of parts back into the system by the action of the absorbents. At first, it may be difficult to conceive how a part of the body can be removed by itself: but there is not more difficulty in conceiving this, than how the body can form itself. Both facts are equally well confirmed. When it becomes necessary that some whole living parts should be removed, it is evident, says Mr. Hunter, that nature, in order to effect this object, must not only confer a new activity on the absorbents, but must throw the part to be absorbed into a state which yields to this operation. The absorption of whole parts in disease arises from five causes: pressure; irritation of stimulating substances; weakness; inutility of parts; death of them.—(*Hunter on Inflammation, &c. p.* 442—446.)

Ulceration takes place much more readily in the cellular and adipose substance, than in muscles, tendons, ligaments, nerves, and blood-vessels. Hence, in the progress of pus to the surface of the body, ulceration often takes a circuitous course for the purpose of bringing the matter to the skin. The skin itself, also, being highly organized, considerably retards the bursting of abscesses. On the same account, when ulceration is spreading, the edges of the skin hang over the ulcerated surface.—(*Hunter, p.* 447—449.) Parts at a considerable distance from the source of the circulation are generally more disposed to ulcerate, than others situated nearer to the heart: hence, one reason of the greater number of ulcers on the lower extremities, than on the arms.

New-formed parts, such as cicatrices, callus, and all adventitious new matter, like tumours, readily admit of being absorbed. Thus, in Lord Anson's voyage, when the crew of the ship began to suffer from great privations, fatigue, the scurvy, &c., it was remarked, that such men as had had ulcers and broken bones formerly, became again disabled by their old sores breaking out afresh, and the callus of their old fractures being removed. The adventitious matter is even more prone to be absorbed than that which is a substitute for the old. Mr. Hunter explained this circumstance on the principle of weakness.

When ulceration takes place in consequence of the death of an external part, it occurs first on the outer edge, between the dead and living substance.

A tumour, when it makes equal pressure in every direction around, will only make its way in an external course, because what Mr. Hunter termed interstitial absorption happens in no other direction.—(*P.* 449.)

The parts situated between an abscess, or any extraneous substance, and the nearest surface, are those which are most susceptible of ulceration. This is one of the most curious phenomena connected with the process under consideration. It shows that there is a principle in the human body by which parts are always prone to free themselves from disease. Slight pressure from without will often produce a thickening of parts, and hence, Mr. Hunter remarks, there even appears to be a corresponding backwardness to admit disease.—(*P.* 449.) Both these facts, he observes, are shown in the case of fistula lachrymalis; for, though the matter is nearest the cavity of the nose, still it makes its way externally, by means of ulceration, while the Schneiderian membrane even becomes thickened, so as to become a barrier against the progress of the disease inward.—(*P.* 451.)

Not unfrequently, as Sir A. Cooper has remarked, matter forms behind the sternum, close to the pleura and pericardium, which membranes are extremely thin. From the proximity of these membranes, it might be expected, that the matter would generally open into the pleura, and, by discharging itself into the cavity of the chest, destroy life. Instead of this result, however, the pleura undergoes no other alteration than that of becoming thickened; and while it is acquiring this addition of substance, the process of absorption is going on in the inner part of the sternum, an aperture is formed through it, and the matter is voided externally. The same fact is exemplified in abscesses between the peritoneum and abdominal muscles. Abscesses of the liver, however, generally burst into the stomach or bowels, which are nearer to them than the skin, and afford also a passage for their evacuation.—(*Lectures, vol.* 1, *p.* 132.)

There is one difference between the advancement of an encysted tumour to the surface of the body, and the progress of an abscess in the same direction, viz. that the former does not excite ulceration of the cyst, but an interstitial absorption of the sound parts, between the cyst and skin, till the cyst and external skin come into contact, at which period inflammation takes place, and absorption becomes accelerated into ulceration. In an abscess, the progressive ulceration begins in the cyst, at the same time that the interstitial absorption in the sound part covering the matter is going on.—(*P.* 452—457.)

The action of progressive absorption is to remove surfaces contiguous to irritating causes, which Mr. Hunter referred to pressure, irritation, and weakness. In cases of tumours, pressure becomes a cause. The buttocks and hips of persons who lie long on their backs often ulcerate. The heels of many patients with fractures, who lie for a great while in the same position, are apt to ulcerate. In the latter instances, Mr. Hunter conceived, that ulceration is a substitute for mortification, and is, at the same time, a proof of a certain degree of strength; for, if the patient's constitution were very weak, the same parts would mortify.—(*P.* 453.) That pressure is a frequent cause of ulceration, is also evinced by the occasional effects of chains on prisoners, and harness on horses.

That irritating substances produce ulceration, needs no illustration.

Progressive absorption may occur either with or without suppuration. We have instances of the latter in cases of extraneous bodies, which travel about

the body, without producing irritation enough to give rise to the secretion of pus. In the progress of aneurisms of the aorta, and of fungous tumours of the dura mater to the surface, the same fact is also illustrated. —(*P.* 455.)

Absorption with suppuration, in other words, ulceration, either happens in consequence of suppuration already begun, in which event the pus acts as pressure; or else absorption attacks external surfaces from particular irritations, or weakness, in which case suppuration must follow.—(*P.* 456.)

The production of ulceration requires much greater pressure from without than from within. The process is always disposed to take place more quickly when near the surface of the body; and its progress becomes accelerated in proportion as it arrives near the skin.

The adhesive inflammation precedes the suppurative, and prevents the pus from becoming diffused as soon as it is secreted; and when the cyst afterward ulcerates, in order to let the matter approach the skin, the adhesive inflammation still continues to go before the ulcerative process, and thus prevents the matter from insinuating itself into the interstices of the cellular substance. —(*P.* 457.)

The pain of ulceration is, in some degree, proportioned to its quickness. When ulceration begins on a surface, or takes place for the purpose of bringing matter to the skin, the pain is always considerable. When ulceration takes place, in order to separate a dead part, as in sloughing, exfoliations, &c., there is seldom any particular pain.—(*P.* 459.)

The ulcerating sore always exhibits little cavities, while the edge of the skin is scalloped, and thin, at the same time turning a little out, and overhanging, more or less, the ulcerated surface. The face of the sore appears foul, and the discharge is very thin.

When ulceration stops, the edges of the skin become regular, smooth, a little rounded, or turned in, and of a purple colour, covered with a semi-transparent white. —(*Hunter on Inflammation, &c. p.* 460.)

The reader, desirous of farther information, should particularly consult this last publication, and *Thomson on Inflammation, p.* 349, *&c.*

ULCERS. Surgeons usually define an ulcer to be a solution of continuity in any of the soft parts of the body, attended with a secretion of pus, or some kind of discharge. "A granulating surface, secreting matter," has been proposed as a definition (*A. Cooper, Lectures, &c. p.* 182), which is very applicable when ulcers have formed granulations, but cannot include case, in which the effects of ulceration are extending, and the granulating process has not yet commenced.

In the present part of this Dictionary, there will not be occasion to speak of several kinds of sores, which have been treated of in other articles.—(See *Cancer, Cancrum Oris, Chilblain, Fistula, Hospital Gangrene, Lupus, Ozæna, Scrofula, Sinus,* and *Venereal Disease.*)

Ulcers are divided into *local* and *constitutional.* As Professor Thomson has well observed, however, it is only within certain limits that this distinction is well founded; for an ulcer, which is at first completely ocal, may in time affect the system so as to become constitutional; and ulcers, which derive their origin from some general affection of the system, may remain after the removal of the constitutional disorder by which they were originally produced.—(*Lectures on Inflammation, p.* 427.)

"Ulcers (says Dr. Thomson) have usually been distinguished from each other by the causes by which they are induced, by the symptoms which they exhibit, and by the parts of the body in which they occur. The want of a disposition to heal in a suppurating surface may depend upon some specific action in the cause from which it proceeds, upon something peculiar in the constitution of the patient in whom it exists, or merely upon an improper mode of management: and hence the distinction that has long been made of ill-conditioned sores or ulcers, into those which are *specific* in their nature, and into those which are *simple.*

"Specific sores or ulcers may be occasioned by specific poisons, or by particular diathesis. The sores or ulcers, which arise from specific poisons, may be either *local*, that is, confined, like a primary syphilitic ulcer, to one spot; or *constitutional*, that is, liable to occur in any part, texture, or organ, such as secondary syphilitic ulcers. Of diatheses predisposing to ulcers we have examples in the scrofulous, scorbutic, and arthritic diatheses, and also in the syphiloid diathesis, or that which arises not unfrequently in those who have had syphilis, from the too free and injudicious use of mercury.

"Every ulcer, strictly speaking, is of a local nature; but there are ulcers which, though necessarily local in their appearance, are connected with, or dependent upon, diseases which affect the general system. These ulcers ought to be regarded as modifications of or forms in which the diseases appear, with which they are connected. Considered in this light, it is obvious that specific ulcers can be treated of with propriety only under the head of the diseases to which they respectively belong.

"We call those ulcers *simple* which do not appear to proceed from any specific disease or morbid diathesis existing in the constitution of those in whom they take place. They are usually solitary occurrences, and the consequences of accidental injuries and improper modes of management. They may occur in every part of the body, but they appear most frequently upon the lower extremities."

Professor Thomson afterward remarks, that "the appearances which different ulcers exhibit, seem, at first view, to afford an excellent foundation for distinctions among them, and so they undoubtedly do in many respects."

"But (says he) it is to be regretted, that the characters upon which the distinctions of ulcers, as well as of many other local diseases, are founded, are neither very uniform in their appearance, nor very easily distinguishable from one another. Not only are the local appearances which present themselves in simple ulcers liable to great variations in the different stages of the same individual affection, but they are often apparently the same with, or at least not easily distinguishable from, those which occur in specific diseases, and which require for their cure peculiar modes of treatment. It is this circumstance which renders it so necessary for us, in endeavouring to distinguish and to cure ulcers, to avail ourselves of all the information which we can procure from the history of the ulcer, from the nature of the exciting cause by which it has been induced, and from the effects of the remedies which have been employed, as well as from the particular appearances which the ulcer itself exhibits."

In noticing another ground of distinction among ulcers, or that derived from the parts in which they occur, Dr. Thomson observes, that "every texture and organ of the body possesses physical and vital qualities peculiar to itself; and these qualities must necessarily modify the appearances which each texture and organ respectively exhibits in the state of disease. Specific diseases render some parts more liable than others to attacks of ulceration. Thus secondary syphilis appears most frequently in the throat; scurvy in the gums; cancer in the lower lip; and lupous and scrofulous ulcerations in the upper lip or in the nose. Cancer seldom or never appears primarily in the upper lip; but syphilis, when it attacks this part, puts on many of the appearances of cancer;" a fact which Dr. Thomson says, he first learned from Mr. Pearson. —(*On Inflammation, p.* 427—430.)

In the valuable treatise on ulcers published by Sir Everard Home, these complaints are divided into six principal kinds, viz.:

1. Ulcers in parts which have sufficient strength to carry on the actions necessary for their recovery.

2. Ulcers in parts which are too weak for that purpose.

3. Ulcers in parts whose actions are too violent to form healthy granulations, whether this arise from the state of the parts or of the constitution.

4. Ulcers in parts whose actions are too indolent, whether this arise from the state of the parts or of the constitution.

5. Ulcers in parts which have acquired some specific action, either from a diseased state of the parts or of the constitution.

6. Ulcers in parts which are prevented from healing by a varicose state of the superficial veins of the upper part of the limb.

Although I have chosen, in the subsequent columns, to adopt this nomenclature, I am perfectly aware of its being on some accounts objectionable, but especially because it assumes hypotheses, the truth of which can

never be established nor proved. This is one of the considerations which have induced Professor Thomson to prefer the old names.—(*Op. cit. p.* 435—438.)

OF ULCERS IN PARTS WHICH HAVE SUFFICIENT STRENGTH TO CARRY ON THE ACTIONS NECESSARY FOR THEIR RECOVERY: SIMPLE PURULENT, OR HEALTHY ULCERS.

In this species of ulcer, the pus is of a white colour, thick consistence, and readily separates from the surface of the sore, and when diluted and examined in a microscope, is found to be made up of small globules, swimming in a transparent fluid. The granulations are small, florid, and pointed at the top. As soon as they have risen to the level of the surrounding skin, those next to the old skin become smooth, and are covered with a thin, semi-transparent film, which afterward becomes opaque and forms cuticle.

In the treatment, it is only necessary to keep the surface clean, and prevent the natural processes from being interrupted. Sir E. Home observes, that this is in general best done by the application of dry lint, for the purpose of absorbing and retaining the matter, which serves as a soft covering for the granulations, and by putting over the lint a pledget of any simple ointment, in order to hinder the matter from evaporating, by which means the dressings will not become adherent, and may be easily taken off as often as requisite.

Although healthy ulcers require no medicated application to be made to them, the dressings must be such as do not disagree with the granulations or surrounding skin.

In some patients, a roller, applied with moderate tightness, with a view of retaining the dressings, will cause uneasiness, and make the ulcer lose its healthy appearance. Sir E. Home has seen several cases of this kind, in which the proper appearance of the sore returned as soon as the bandage was discontinued.

In some patients, ointment irritates and inflames the neighbouring skin; and certain superficial ulcers will not heal while kept in a moist state, and unexposed to the air; but heal when allowed to become dry and covered with a scab.

These particularities are referred by the preceding author to constitutional causes, and not disease; for the ulcers heal as soon as the particular things which disagree with them are discontinued. These peculiarities in certain healthy sores may also attend others of a different description, and should always be discriminated from the effects of disease.

1. Applications in the form of vapour, and fomentations, should never be employed, as they render the texture of the granulations looser, and diminish the disposition to form skin.

2. With respect to fluid applications, Sir E. Home also very properly condemns poultices, as well as fomentations. He speaks of alcohol as being an application which promotes the formation of a scab, when this mode of cure is chosen.

3. In regard to ointments, their only use, in cases of healthy ulcers, is to keep the matter from evaporating. The most simple ointments are the best for the purpose; particularly the one composed of white wax and olive oil.

Sir E. Home observes, that the great objections to the common simple ointments are, that they sometimes disagree with the skin, even when recent and free from all rancidity. When they have acquired the latter quality, they still more frequently create a greater degree of irritation.

4. With respect to applications in the form of powder, Sir E. Home remarks, that when it is desirable to form a scab on the ulcer, any inert powder may be sprinkled on the sore; but he prefers dry lint. Nothing should touch the powder or lint; and to prevent this circumstance, Sir E. Home recommends applying a little bolster on each side of the sore, and over them a roller, which will go from one bolster to the other in the manner of a bridge.

For healthy ulcers, dry lint is to be regarded as being upon the whole the most eligible application. When the sore does not secrete pus enough in twenty-four hours to moisten the lint, the dressings are to be changed only every other day.

When a moderately tight bandage is not forbidden by constitutional peculiarities, it is useful both in supporting the muscles and skin, which are often in a flabby state from the unexercised state of the limb, and in defending the newly-formed parts.

ULCERS IN PARTS WHICH ARE TOO WEAK TO CARRY ON THE ACTIONS NECESSARY FOR THEIR RECOVERY.

This is the second of the classes into which Sir Everard Home has divided ulcers in general.

The granulations of these sores are larger, more round on their external surface, and of a less compact texture, than those formed on ulcers in healthy parts. Sir E. Home has also noticed their semi-transparent appearance. When they have filled up the cavity of an ulcer to a level with the surface of the body, they do not readily form skin, but, rising up in a still higher manner, often lose altogether the power of producing new cutis. When the parts are still weaker, the granulations sometimes continue gradually to fill up the hollow of the ulcer, and then, all on a sudden, are suddenly absorbed, so as to leave the sore as deep as it was before.

Ulcers may be weak from the first, or become so in the progress of the case. Even granulations of the most healthy kind, if they are not skinned over in a certain time, gradually lose their primitive strength.

Sores on the legs are greatly under the influence of all natural peculiarities of the constitution, and every thing which affects the health. When the constitution becomes in the least weaker or stronger, the appearance of the granulations becomes changed accordingly, and this effect of constitutional weakness or strength, on ulcers, is greater in proportion as the sores are farther from the source of the circulation.

While the constitution is undergoing any kind of disturbance, the healing of an ulcer is suspended Mental anxiety is very apt to retard cicatrization.

Such effects of the constitutional kind on ulcers are greater in weak and delicate persons than in the strong and robust. Change of weather has considerable influence over the healing of sores. Sir E. Home mentions, in proof of this fact, that when there were several hundreds of ulcers in the Naval Hospital at Plymouth, in 1778, every time the weather changed from a dry to a moist state, the ulcers universally assumed an unhealthy appearance; but put on a better aspect when the weather became dry again.

In the treatment of this kind of ulcer, tonics are to be exhibited, particularly bark and steel, and every thing which disagrees with the constitution is to be avoided. Wine and cordial medicines are also usually prescribed. Porter, however, is deemed better than wine for working people.

Sir E. Home observes, that the first object in the local part of the treatment, is to keep the granulations from rising above the edge of the surrounding skin. This gentleman (in my opinion) very judiciously represents the greater propriety of preventing the granulations from ever becoming too high by the employment of proper applications, than following the common plan of destroying the high granulations with escharotics, after they have risen to an improper height. There cannot be the smallest doubt, that if the granulations could always be prevented from rising up too much, the patient would suffer a great deal less pain.

Instead of applying to the surface of the ulcers now under consideration lunar caustic, blue vitriol, or red precipitate, Sir E. Home prefers mixing these escharotics with other substances, so as to render them only strong stimulants, and using them in this latter form He conceives that when the high granulations are destroyed with escharotics, the disposition of the surface underneath to reproduce them is increased, but that this is not the case when the luxuriant parts are only stimulated so as to become absorbed. He believes that when animal substances grow with great rapidity they are, like vegetable ones, weaker than when produced in a slower manner. Hence he is of opinion, that the growth of granulations ought to be checked in the early stage of their formation, by some resistance which they are just able to overcome; under which circumstances they derive strength from the limited increase of action which they are obliged to undergo.

On the same principle, according to Sir E. Home, the pressure of tight bandages is advantageous, and ulcers which heal while the patient is walking about,

are not so apt to break out again as others healed while the parts are in a state of perfect rest.

In the treatment of these ulcers, when the granulations have come to a proper height, and do not form a thin, semi-transparent pellicle upon their surface, they are to be considered as weak parts and treated accordingly. In this circumstance, when no particularity of constitution forbids, Sir E. Home recommends pressure made with a thin piece of lead over the dressings, and supported with a tight bandage.

Among the impediments to the healing process, Sir A. Cooper notices the *languid state of a sore*, denoted by the glassy, semi-transparent appearance of the granulations already described. The dressings enumerated by him for the improvement of an ulcer in this condition are, the ung. hydr. nitrico-oxydi, which, however, is said to produce a thickening of the cuticle at the edge of the sore, preventing the growth of the granulations at that part, and requiring the application of the ung. hydr. fort. for its correction; a lotion of the sulphate of zinc, two grains to one ounce of water; a solution of the sulphate of copper, one grain to an ounce of water; and a solution of one grain of oxymuriate of mercury in an ounce of lime-water. A roller is to be applied, the diet is to be nutritious, and the patient to take exercise.—(*Lectures*, *vol.* 1, *p.* 187.)

OF APPLICATIONS TO ULCERS ATTENDED WITH WEAKNESS.

Although strictly we have no topical applications which can directly communicate strength to granulations, there are certainly some which prevent the granulations from exhausting themselves by luxuriant growth, and stimulate them to draw more blood from the arteries, which effects, as Sir E. Home remarks, render such granulations stronger.

1. This gentleman very properly condemns as applications to weak ulcers, all relaxing fomentations commonly employed; and recommends, instead of them, the use of spirits of wine and the decoction of poppies in equal proportions, not, however, to be applied hot.

2. With regard to moist applications, the same gentleman expresses his disapprobation of poultices; and mentions a weak solution of the argentum nitratum, as the most eligible application in an aqueous form.

3. On the subject of powdered substances as applications to weak ulcers, Sir E. Home says he has often tried bark and the lapis calaminaris, without perceiving that the former had any power of strengthening granulations, or the latter any virtue in disposing them to form new skin; properties commonly imputed to these applications.

Sir E. Home entertains no better opinion of plaster of Paris or powdered chalk, employed with the view of promoting the formation of skin. Powdered carbon he speaks of as being more adapted to irritable than weak ulcers. He praises powdered rhubarb as particularly applicable to the latter kind of ulcer, because it represses the luxuriant growth of the granulations, renders them small and compact, and disposes them to form skin. When, however, the granulations have risen above the level of the skin, it is not powerful enough to reduce them. When the rhubarb is too stimulating, it is to be mixed with a fourth part of crude opium in powder.

A piece of lint, a little less than the sore, is always to be put over the powder, and covered with a pledget of simple ointment.

4. Ointments, according to Sir E. Home, are particularly apt to disagree with weak ulcers. When other applications fail, however, greasy ones may be tried, and the above gentleman gives a preference to the ung. hydrarg. nitrat., mixed with hog's lard, in the proportion of one to five, or else to common cerate, blended with a small quantity of the hydrarg. nitrat. ruber.

OF ULCERS IN PARTS WHOSE ACTIONS ARE TOO VIOLENT TO FORM HEALTHY GRANULATIONS, EITHER FROM THE STATE OF THE PARTS, OR THE CONSTITUTION: IRRITABLE, GANGRENOUS, OR SLOUGHING ULCERS.

There are three states of the constitution influencing the nature of ulcers: an irritable state, in which all the actions of the animal economy are more rapid than in health; an indolent state, in which they are unusually languid; and, lastly, a diseased state, by which they are affected.

An irritable and an indolent ulcer cannot in general be distinguished from each other by mere appearances, though they may be so in a few instances. Sir E. Home informs us, that the disposition of an ulcer, like the disposition of a constitution, can only be accurately ascertained by determining the actions which arise from the different impressions made upon it.

The following appearances, he says, at once show the ulcer to be of an irritable kind. The margin of the surrounding skin being jagged, and terminating in an edge which is sharp and undermined. The bottom of the ulcer being made up of concavities of different sizes. There being no distinct appearance of granulations, but a whitish spongy substance covered with a thin ichorous discharge. Every thing that touches the surface gives pain, and very commonly makes it bleed. The discharge is altered from common pus to a thin fluid, in proportion to the degree of irritability communicated to the sore by constitutional causes. In general, the pain of an irritable sore gradually becomes less. When it is not constant, but comes on in paroxysms chiefly in the evening, or night-time, with great violence, convulsive motions of the limb are apt to occur, and extend to various other parts. Sir E. Home refers this symptom to irritation communicated along the course of the nerves, and producing an action in them, attended with a violent contraction of the muscles which they supply.

When the above-mentioned signs of an irritable ulcer are not present, we must form a judgment of the nature of the sore from listening to the history of the case, the effects of various applications, &c. When this kind of information cannot be obtained, Sir E. Home recommends the treatment to begin on the supposition of the ulcer being of an irritable nature.

The *gangrenous* or *sloughing* ulcer is frequently only one stage of the irritable one, and is therefore frequently met with in persons whose constitutions have been hurt by intemperance. It occurs also, as Sir A. Cooper has related, among persons emaciated and reduced by extreme want. The surface of the sore is dry, its edges have a livid appearance, with small vesicles on them, and the patient suffers much from irritative fever.

When an ulcer occurs just over the malleolus externus, it is generally of an irritable kind, in consequence of the nature of the part on which it is situated, quite independently of any constitutional or local disposition to irritability. Sir E. Home conceives that the periosteum, which here lies immediately under the skin, becomes the seat of the ulcer, is the cause of its being very difficult to heal, and gives it the irritable appearance. The fact that sores situated on the ligament of the patella, and over the periosteum of the anterior surface of the tibia, assume a similar appearance, and are equally difficult to heal, made him more confirmed in his sentiment.

As internal medicines in these cases, Sir A. Cooper praises calomel and opium: one grain and a half of the former, and one of the latter, morning and evening. By some practitioners, the compound decoction of sarsaparilla seems also to be regarded as a good medicine for lessening constitutional irritability.—(*Lectures*, *&c. vol.* 1, *p.* 195.)

In treating ulcers in general, the surgeon will find it advantageous to be acquainted with the effects of a great many external applications; for very few cases will continue to heal beyond a certain time, without some alteration in the treatment. The necessity of changing the applications after they have been continued for a certain time, is strikingly illustrated by the fact, that leaving off a powerful application and employing one which at first would have had no effect, often does a great deal of service. When the change is made to a medicine of powers equal to those of the previous one, the benefit will be more lasting than in the preceding circumstance.

OF APPLICATIONS TO IRRITABLE ULCERS.

1. Sir E. Home recommends applications in the form of vapour, as being particularly useful by their quality of allaying irritation and soothing pain.

The steam of warm water is productive of benefit in this way, though seldom used by itself. Its good effects are increased when it is mixed with spirits.

Sir E. Home speaks also in favour of the benefit derived from fomentations containing opium; such as the tincture of opium sprinkled on flannel, wrung out of warm water; or the application of flannels wet with a warm solution of the extract of opium, or with a decoction of poppy-heads. A decoction of chamomile flowers, the tops of wormwood, or hemlock leaves may also be employed for the same purpose.

Sir E. Home points out particular irritable ulcers, however, which are rendered more painful by warm applications; and he states that the sores alluded to are generally attended with a mottled purple discoloration of the limb, for some way from them, and a coldness of the lower part of the leg, and that they are often disposed to mortify, which event is promoted by warmth.

2. As for moist applications, the poultice made of linseed meal is the most simple, and most easily made; and, as it does not necessarily require any addition of oil, is to be preferred when this disagrees with the sore.

Sir E. Home does not say much in favour of the use of the liquor plumbi acetatis, in poultices; for, though he allows that it often answers very well, he adds that it also frequently disagrees with the ulcer, and, if long used, is apt to bring on the lead-colic.

A decoction of poppy-heads is said to be a very good liquor for making poultices.

The carrot-poultice is also found to agree with a great many irritable sores. I sometimes add to it the opium lotion.

The great objection to poultices in these cases, being the weight of such applications, the limb should always, if possible, rest upon the poultice, and not the poultice upon the limb.

If poultices be employed, their use is to be continued as long as the granulations are small, and the ulcer is rapidly diminishing in size, and this even till the cicatrization is complete. When the granulations become large and loose in their texture, poultices should be left off.

When the weight of poultices prohibits their use, Sir E. Home advises the trial of lint, dipped in one of the following lotions, and covered with a pledget of some simple ointment: a solution of the extract of opium; a decoction of poppies; the tincture of opium; a decoction of cicuta; the liquor plumbi acetatis dilutus; or a weak solution of the argentum nitratum.

3. Powdered applications are generally too stimulating for irritable ulcers. Carbon has been found useful; so has powdered extract of opium mixed with an equal quantity of carbon or linseed flour. However, opium occasionally affects the constitution, in consequence of absorption, and it has been known to excite violent inflammation, ending in mortification.

4. Ointments are not often proper applications for irritable ulcers, as they are always more or less rancid, and generally disagree with the skin.

According to Sir A. Cooper, however, the following ointment agrees well with such cases: ℞. Ung. cetacei, ung. hydr. nit. ää ʒss. Pulv. opii ʒj. M.—(*Lectures*, *vol.* 1, *p.* 194.)

Sir E. Home mentions cream as being a very useful application, particularly in cases in which warmth is found to do harm. As a substitute for it he recommends an ointment composed of hog's lard, purified by being repeatedly washed in spring water, and then mixed with a small quantity of white wax and rose-water.

The observations made respecting solutions of lead apply to the unguentum cerussæ acetatæ.

5. The pressure of bandages is generally hurtful to irritable sores, though a slight degree of it proves serviceable to certain ulcers which are somewhat less irritable and arise from weakness.

When the ulcer is *gangrenous* or *sloughing*, the best application is the nitric acid lotion (50 drops of the acid to a quart of water). Lint is to be dipped in it, laid over the sore, and then covered with a piece of oiled silk, so as to keep it wet several hours. The recumbent posture is to be observed.—(*Sir A. Cooper*, *Lectures*, *&c. vol.* 1, *p.* 191.) This gentleman also gives internally, three times a day, twenty drops of the tincture of opium, and 10 gr. of carbonate of ammonia, with an ounce and a half of camphor mixture, and a little of the compound tinct. of cardamom seeds. Here the exhibition of morphine might be advantageous.

OF ULCERS IN PARTS WHOSE ACTIONS ARE TOO INDOLENT TO FORM HEALTHY GRANULATIONS, WHETHER THIS INDOLENCE ARISES FROM THE STATE OF THE PARTS, OR OF THE CONSTITUTION: THE CALLOUS ULCERS OF SEVERAL WRITERS.

The indolent ulcer forms in its appearance a complete contrast to the irritable one. The edges of the surrounding skin are thick, prominent, smooth, and rounded. The surface of the granulations is smooth and glossy. The pus, instead of being of a perfect kind, is thin and watery, being composed of a mixture of pus and coagulating lymph. The lymph consists of flakes, which cannot be easily separated from the surface of the sore. The bottom of the ulcer forms quite a level, or nearly so, and, as Sir E. Home very accurately remarks, the general aspect conveys an idea that a portion of the skin and parts underneath has been removed, without the exposed surface having begun any new action to fill up the cavity.

When, however, the indolence of the ulcer is not so strongly marked, the sore does not correspond to the preceding description, but resembles in appearance the ulcer, which possesses an inferior degree of irritability, and can only be discriminated from it by receiving no benefit from soothing applications.

The odd circumstance of some indolent sores having the appearance of irritable ones is, in some degree, explained by ulcers always being influenced by changes in the constitution, and accidental circumstances affecting the parts.

Most of the ulcers seen in the London hospitals are of the indolent kind. An indolent disposition in an ulcer may proceed altogether from the long existence of the disease; and hence, Sir E. Home very justly observes, it is immaterial whether at first it were healthy, weak, or irritable; for, if not cured within a certain time, it becomes indolent, with the exception of a few of the irritable kind, which never change their nature.

Indolent sores do form granulations; but these, every now and then, are all on a sudden absorbed, and, in the course of four-and-twenty hours, the sore becomes as much increased in size as it had been diminished in as many days or weeks. This absorption of the granulations arises principally from their not being of a healthy kind; but the event is promoted by changes in the weather, anxiety, fatigue, &c.

The object in the treatment of indolent ulcers is not simply to produce a cure, but to render such cure as permanent as possible. This can only be accomplished by altering the disposition of the granulations, and rendering them strong enough to stand their ground after the ulcer is filled up.

When an ulcer which has existed six months is dressed with poultices for a week, the granulations at the end of this time will partly have filled up the hollow of the sore, but they will present a large, loose, and glossy appearance. Should the poultice be now discontinued, and some proper stimulating application used for another week, the granulations will be found, at the expiration of this time, to have become smaller, more compact, redder, and free from the glossy appearance. The ulcer, when healed by the latter application, will not be so likely to break out again, as when healed with large, loose, flabby, glossy granulations.

Sir E. Home states, that the number of indolent sores which healed under the use of stimulating applications, and do not break out again, compared with similar cases treated with mild dressings, are as four to one.

APPLICATIONS TO INDOLENT ULCERS.

1. Medicines in the form of vapour cannot heal indolent sores so as to accomplish a lasting cure. It is only when these ulcers assume a foul appearance, and are in a temporary state of irritation, that such applications can be advantageously employed.

In general, patients on their first admission into hospitals with sore legs, have their ulcers in a temporary state of irritation from neglect, exercise, excesses, &c. Hence, it is commonly found advantageous for the first few days or even a week, to have recourse to poultices and fomentations.

I believe that any common fomentation, whether of chamomile, poppy-heads, or mere warm water, answers equally well. The time for using it is while a

fresh poultice is preparing, and this latter application should be changed twice a day.

2. Moist applications, such as poultices, are to be employed when fomentations are proper, and they may be made of bread, oatmeal, or linseed.

Sir E. Home describes a species of indolent ulcers which occur in patients of debilitated constitutions, which put on a sphacelated appearance without any apparent cause, even after they have made some progress towards a cure, and in this way spread to a very large size. Some of these ulcers, if judged of from their appearances, would be ranked as irritable ones; but, as soothing applications do not agree with them, they are not to be classed with the latter kind of sores. They are said to occur particularly in seamen and soldiers who have been long at sea, and have been termed *scorbutic* ulcers. Sir E. Home represents them, however, as not being necessarily connected with the scurvy, and being often met with in patients who have not been on the sea. He states that they are not of necessity joined with any specific disease; but are common to all kinds of patients whose constitutions have been impaired, either by salt provisions, warm climates, or drinking.

From some trials, first made by Dr. Harness, and afterward by Sir E. Home, it appears that these particular ulcers, when in a sphacelated state, are benefited by employing the gastric juice of ruminating animals as an external application. It makes the sloughs fall off, and the sore assume a better appearance. Some pain follows on its being first applied, and it is to be regarded as a stimulating application.

Sir E. Home mentions, that in the West Indies, such ulcers are advantageously dressed with the fresh root of the cassada, grated into a pulp. Lime-juice has also been found a useful application, and solutions of the sulphate of copper and alum have been recommended.

When indolent ulcers are not attended with certain peculiarities, a solution of the argentum nitratum is one of the best of the watery applications. It stimulates the granulations, and makes them put on a more healthy appearance, and its strength may be increased according to circumstances. An ulcer which at first cannot bear this solution above a certain strength without pain, and without the granulations being absorbed, becomes able, after the application has been used about ten days or a fortnight, to bear it twice as strong without such effects being produced: a proof of the granulations having acquired strength.

The tincture of myrrh is often employed as an application to indolent ulcers. Hunezowsky has praised a decoction of the walnut-tree leaves, and soft covering of the walnut for the same purpose.—(*Acta Acad. Med. Chir. Vindob. t.* 1, 1788.) Sir E. Home gives his testimony in favour of both the latter dressings.

Diluted sulphuric acid and the expressed juice of the pod of different species of pepper in a recent state, are mentioned by Sir E. Home as having been used as applications to indolent ulcers: the latter in the West Indies.

This gentleman recommends also a scruple of nitrous acid, mixed with eight ounces of water, as a very useful medicine for external use. The strength must be increased or diminished according to circumstances. Sir E. Home has found that this application promotes, in a very uncommon manner, the progress of the cure.

The first application of diluted nitrous acid gives a good deal of pain, which lasts about half an hour and then goes off.

When an indolent ulcer heals with the diluted nitrous acid, the process of skinning is accomplished with more rapidity than when other applications are employed; and the new skin is said to be more completely formed. The acid coagulates the pus as soon as it is secreted.

Sir E. Home states, that several patients who had ulcers dressed with the diluted nitrous acid, were allowed to walk about without finding the progress of the cure retarded, although no bandage to support the limb was made use of. The same surgeon informs us, also, that in ulcers of the leg, attended with an exposure of a piece of bone, which retards the cure, because it does not exfoliate and come away, the application of diluted nitrous acid to the bone removes the earthy part, and excites the absorbents to act upon the remaining animal portion.

3. The only application in the form of powder adapted to indolent ulcers is, according to Sir E. Home, the hydrargyrus nitratus ruber. It may be occasionally used for ulcers of the most indolent kind.

4. Ointments are represented as being particularly good applications for indolent sores.

The idea of the air having bad effects on sores which are exposed to it, is now disbelieved. That air has no irritating property of this kind is proved by the fact, that when the abdomen of an animal is filled with it, no inflammation is excited. When the cellular membrane is loaded with it, in cases of emphysema, the parts do not afterward inflame. Nor do ulcers in the throat, as Sir E. Home justly remarks, heal less favourably than others, although they are of necessity always exposed to the air.

Whatever ill effects arise may probably be explained by the consequences of evaporation, which converts the soft pus into a scab. The granulations are, in all probability, most favourably circumstanced when they are covered with their own matter, which should only be now and then removed, in order that such applications may be made as will stimulate them to secrete a more perfect pus. From what has been just stated, it must be obvious that indolent ulcers should not be frequently dressed, and that if they are so, and the dressings are stimulating, the practice will do harm. Changing the dressings once in twenty-four hours is deemed quite sufficient, unless the quantity of matter be very great, which seldom happens.

One part of the unguentum hydrargyri nitrati, mixed with three of hog's lard, is one of the best applications. Its strength, however, must be gradually increased.

The unguentum hydrargyri nitrati has the effect of quickly removing the thickness of the edges of indolent ulcers, and the surrounding dark-red colour of the skin. It seems also to have particularly great power in making the granulations become small and healthy, and of course the ulcer less likely to break out again.

With some ulcers, however, this ointment is found to disagree.

The ceratum resinæ and the unguentum elemi, mixed with the balsam of turpentine, or that of copaiba, are other common applications to indolent sores. Sir E. Home states, that the resins and turpentines are not so powerful as the acids and metallic salts, in giving the granulations a healthy appearance, and a disposition to resist absorption.

Cases attended with a degree of indolent thickening are most likely to be improved by camphorated ointments.

In numerous cases, the applications, whatever they are, soon lose their effect, and others should then be substituted for them. The past and present states of the sore are always to be considered. Although the ulcer may be in its nature indolent, it is liable to temporary changes from constitutional causes, and hence, a temporary alteration in the treatment becomes proper.

5. Bandages are undoubtedly of essential service in healing many kinds of ulcers; but their efficacy is so great in curing numerous indolent sores, that they are sometimes considered the principal means of cure. Among modern advocates for rollers, the late Mr. Whately was one of the most zealous. While this gentleman acknowledged that the efficacy of *pressure* in counteracting the effects of the dependent posture was known to Wiseman, who recommended the use of the laced stocking for this purpose, he conceived that the effects of pressure in the cure of ulcers on the extremities, previously to the appearance of Dr. Underwood's treatise, were not duly insisted upon by surgical writers. However, he confessed, that there always had been practitioners who were acquainted with the importance of this mode of treatment, and adopted it in their practice. He has criticised the work of Sir Everard Home, in which it is remarked, that the effect of pressure is not much relied upon for the cure of these complaints. Indeed, says Mr. Whately, it is stated in that book, not only that no benefit is derived from compression in several species of these ulcers, but that many ulcers are rendered worse, more painful, and more unhealthy in their appearance by its use; truths which it would be impossible for Mr. Whately to refute. They are, I conceive, admitted by himself, when he observes, that there are certain conditions of

an ulcer which will not bear compression. Whether Sir Everard Home has not given a sufficiently favourable account of the effects of pressure in the cure of ulcers of the leg, I will not presume to determine; perhaps he may not have insisted so much upon this treatment as it deserves; but I can find no fault with him for speaking of it as *frequently* injurious, because the fact is notorious.

In the cases published in Mr. Whately's essay *very little variety of dressing was used;* pressure being the principal means of cure, with some exceptions particularly specified in the work.

"I cannot doubt (says Mr. Whately) that the practice here recommended must in the end prevail, notwithstanding it has this great obstacle to contend with, that surgeons must condescend, for the most part, to apply the bandages with their own hands. The clumsy and ineffectual manner in which this business is too frequently done can never be expected to produce the desired effect. I am certain, that if the necessary pains be taken, according to the directions here laid down, such effects will uniformly follow as must convince the unprejudiced mind, that to have recourse to the operation of tying varicose veins, and the application of a great variety of remedies can be *very rarely*, most probably *never*, necessary."

With respect to Mr. Baynton's mode of treatment, while Mr. Whately regards it as a confirmation of the principles insisted upon in his own tract, he considers the plan of making the pressure with adhesive plaster inconvenient, and on several accounts objectionable. In every case related by Mr. Baynton he is sure that the proper application of compresses and flannel rollers would have produced similar good effects. The instances of success by this method, after the supposed failure by the roller, he attributes to the pressure made by the plasters having been applied with Mr. Baynton's own hands, whereas that with the roller was probably so made, that the effect intended by it could not possibly be obtained. No surgeon, he observes, who will not be at the trouble of applying the roller and compresses himself, can be a judge of what may be effected by the proper management of them.

The following is the calamine cerate which Mr. Whately has usually employed:

℞. Axung. porcin. depur. lib. ij.
Empl. plumbi. lib. iss.
Lap. calam. præp. ap. lib. j. M.

"To this formula (says Mr. Whately) I shall add another for making a cerate, which nearly resembles the unguentum tripharmicum of the old Dispensatory, but being less oily, it makes a much more adhesive plaster. It should be spread on rag or silk as an external covering to the dressing on lint, where a tow plaster cannot be conveniently used; as in wounds of the face or hands, a bubo, or any other sore where an external plaster cannot be readily retained in its situation by a bandage. This plaster is likewise so mild, that it never irritates the skin. I have found it also a very useful plaster in fractures. The following is the formula:

℞. Empl. plumbi. lib. j.
Axung. porcin. depur. unc. vj.
Aceti unc. iv. M."

With respect to the proper method of applying the roller and compresses, Mr. Whately offers the following remarks:

"The best width for a flannel roller, designed for those who have slender legs, is three inches: but for those whose legs are of a large size, they should always be three inches and a half in width. They must therefore be at first torn a little wider, that they may be of their proper width when repeatedly washed. It will likewise be found, that rollers made of fine, soft, and open flannel will answer much better than those made of coarse hard flannel.

For those who have full-sized legs, the length of six yards is but just sufficient to answer all the purposes intended by a roller; but in those who have very small legs five yards is a sufficient length. Care should be taken that the rollers be washed in very hot water, and they should be hung up to dry immediately on being washed. If these precautions be not attended to, repeated washing of them will, in some kinds of flannel, make them as narrow as tape, by which they will be rendered almost useless.

In applying a roller, the first circle should be made *round* the *lowest* part of the ankle, as near as possible to the heel; the second should be formed from thence round the foot; the third should be passed again round the foot quite to the toes The roller should then be passed from the foot round the ankle and instep a second time, to make the fourth circle. In doing this, it should be brought nearer (but not over) the point of the heel, than it was at the *first time* of going round this part. The fifth circle should pass over the ankle again, and not more than half an inch higher up the leg than the fourth circle. The sixth, seventh, eighth, and ninth circles should ascend spirally along the small of the leg, at the *exact distance* of three-fourths of an inch from each other. Having proceeded thus far up the leg, we may begin to increase the distances of the circles from each other; they may succeed each other upwards to the knee at the distance of from one to two inches, according to the size and shape of the leg. At that part where the calf of the leg commences, it is generally necessary to let the upper edge of the roller be once, twice, or thrice turned downwards for about half the circumference of the leg, in order to make the roller lie smooth between the middle of the calf and the small of the leg. When the roller has been thus applied as far as the knee, there will be a portion of it to spare, of perhaps a yard in length; this remainder should be brought down by spiral windings at greater distances from each other than those which were made on the ascent of the roller. The windings should in general be completed in the small of the leg, where the roller should be pinned.

In *many* cases it is necessary to apply the roller *over* the *heel*. It should be brought as low as possible round the ankle, as in the former description. From thence the second circle of the roller should pass from the instep over one side of the heel, and be brought over the other side of the heel to the instep again. The third circle should be passed round the ankle a second time, but still nearer to the heel than the first circle was. The roller should after this be brought back to the foot, and passed round it to make the fourth circle. A fifth circle should be again made (though it is not in all cases absolutely necessary) round the foot to the toes. To make the sixth circle, the roller should be brought back, and passed round the ankle again. The seventh, eighth, ninth, tenth, and eleventh circles should ascend spirally at the *exact distance* of three-fourths of an inch from each other; these distances commencing at the sixth circle. The roller should then be carried to the knee and be brought down again to the small of the leg, as described in the former instruction.

In applying the compresses, it is necessary in every instance to put them on one by one, and not all in a mass, though they be of a proper size and number. They should be crossed in different directions; the largest of them should in no case be longer than just to meet on the opposite side of the leg to which they are applied. I have in many instances seen the compresses applied by the patients of such a length as to go round the leg like a roller, and be fastened together with pins. This method generally wrinkles and blisters the skin, and by no means answers the purpose of making a compression on the part where it is most wanted. I never suffer a pin to be used in the compresses. If the same compresses in any case be applied two days together, they should always be turned on the contrary side at each reapplication, in order to prevent wrinkles on the skin."—(See *Practical Obs. on the Cure of Wounds and Ulcers on the Legs without rest, by T. Whately*, 1799.)

6. I shall next introduce an account of Mr. Baynton's plan of curing old ulcers of the leg, by means of adhesive plaster. Were I to say, that any particular method of dressing such sores is entitled to superior praise, I should certainly decide in favour of this gentleman's practice. I have seen it most successful myself, and I hear it highly spoken of by numerous professional friends, in whose unprejudiced judgment I place much reliance.

Mr. Baynton acquaints us, that the means proposed by him will be found, in most instances, sufficient to accomplish cures in the worst cases without pain or confinement. After having been repeatedly disappointed in the cure of old ulcers, he determined *to bring their edges nearer together by means of slips of adhesive plaster*. To this he was chiefly led from having

frequently observed, that the probability of an ulcer continuing sound depended much on the size of the cicatrix which remained after the cure appeared to be accomplished; and from well knowing that the true skin was a much more substantial support and defence, as well as a better covering than the frail one, which is obtained by the assistance of art. But when he had recourse to the adhesive plaster, with a view to lessen the probability of those ulcers breaking out again, he little expected that an application so simple would prove the easiest, most efficacious, and most agreeable means of treating ulcers.

Although the first cases in which Mr. Baynton tried this practice were of an unfavourable nature, yet he had soon the satisfaction to perceive that it occasioned very little pain, and materially accelerated the cure, while the size of the cicatrices was much less than it would have been, had the cures been obtained by any of the common methods.

At first, however, the success was not quite perfect; as, in many instances, he was not able to remove the slips of plaster, without removing some portion of the adjacent skin, which, by occasioning a new wound, proved a disagreeable circumstance in a part so disposed to inflame and ulcerate as that in the vicinity of an old sore. He therefore endeavoured to obviate that inconvenience by keeping the plasters and bandages well moistened with spring water for some time before they were removed from the limb. He had soon the satisfaction to observe, that the inconvenience was not only prevented, but that every succeeding case justified the confidence he now began to place in the remedy. He also discovered that moistening the bandages was attended with advantages which he did not expect; for while the parts were wet and cool, the patients were much more comfortable, and the surrounding inflammation was sooner removed.

By the mode of treatment here recommended, Mr. Baynton found that the discharge was lessened, the offensive smell removed, and the pain abated in a very short time. But besides these advantages, he also found that the callous edges were in a few days level with the surface of the sore: that the growth of fungus was prevented, and the necessity of applying painful escharotics much lessened, if not entirely done away. Mr. Baynton gives the following description of his method.

"The parts should be first cleared of the hair, sometimes found in considerable quantities upon the legs, by means of a razor, that none of the discharges, by being retained, may become acrid, and inflame the skin, and that the dressings may be removed with ease at each time of their renewal, which, in some cases where the discharges are very profuse, and the ulcers very irritable, may, perhaps, be necessary twice in the twenty-four hours, but which I have, in every instance, been only under the necessity of performing once in that space of time.

The plaster should be prepared by slowly melting, in an iron ladle, a sufficient quantity of litharge plaster, or diachylon, which, if too brittle when cold to adhere, may be rendered adhesive by melting half a drachm of resin with every ounce of the plaster: when melted, it should be stirred till it begins to cool, and then spread thinly upon slips of smooth porous calico, of a convenient length and breadth, by sweeping it quickly from the end held by the left hand of the person who spreads it, to the other, held firmly by another person, with the common elastic spatula used by apothecaries; the uneven edges must be taken off, and the pieces cut into slips about two inches in breadth, and of a length that will, after being passed round the limb, leave an end of about four or five inches. The middle of the piece so prepared is to be applied to the sound part of the limb, opposite to the inferior part of the ulcer, so that the lower edge of the plaster may be placed about an inch below the lower edge of the sore, and the ends drawn over the ulcer with as much gradual extension as the patient can well bear; other slips are to be secured in the same way, each above and in contact with the other, until the whole surface of the sore and the limb is completely covered, at least one inch below, and two or three above, the diseased part.

The whole of the leg should then be equally defended with pieces of soft calico, three or four times doubled, and a bandage of the same, about three inches in breadth, and four or five yards in length, or rather as much as will be sufficient to support the limb from the toes to the knee, should be applied as smoothly as can be possibly performed by the surgeon, and with as much firmness as can be born by the patient. It is to be first passed round the leg, at the ankle joint, then as many times round the foot as will cover and support every part of it, except the toes, and afterward up the limb till it reaches the knee, observing that each turn of the bandage should have its lower edge so placed as to be about an inch above the lower edge of the fold below it.

If the parts be much inflamed, or the discharge very profuse, they should be well moistened, and kept cool with cold spring-water, poured upon them as often as the heat may indicate to be necessary, or, perhaps, at least once every hour. The patient may take what exercise he pleases, and it will be always found, that an alleviation of his pain and the promotion of his cure will follow as its consequence, though under other modes of treating the disease, it aggravates the pain and prevents the cure.

These means, when it can be made convenient, should be applied soon after rising in the morning, as the legs of persons affected with this disease are then found most free from tumefaction, and the advantages will be greater than when they are applied to limbs in a swollen state. But at whatever time the applications be made, or in whatever condition the parts be found, I believe it will always happen, that cures may be obtained by these means alone, except in one species of the disease, which seldom occurs, but that will hereafter be described. The first application will sometimes occasion pain, which, however, subsides in a short time, and is felt less sensibly at every succeeding dressing. The force with which the ends are drawn over the limb must then be gradually increased, and when the parts are restored to their natural state of ease and sensibility, which will soon happen, as much may be applied as the calico will bear, or the surgeon can exert; especially if the limb be in that enlarged and compressible state which has been denominated the scorbutic, or if the edges of the wound be widely separated from each other."

Mr. Baynton afterward takes notice of the breaking of the skin near the ulcers; a circumstance which sometimes proved troublesome, and arose partly from the mechanical effect of the adhesive plasters, and partly from the irritating quality of the plaster. Mr. Baynton, however, only considers such sores of serious consequence when they are situated over the tendon of Achilles, in which situation they are sometimes several weeks in getting well. This gentleman recommends, with a view of preventing these ulcers, a small shred of soft leather to be put under the adhesive plaster.

Mr. Baynton next adds, "that cures will be generally obtained without difficulty, by the mere application of the slips and bandage; but when the parts are much inflamed, and the secretions great, or the season hot, the frequent application of cold water will be found a valuable auxiliary, and may be always safely had recourse to, where the heat of the part is greater than is natural, and the body free from perspiration."—(See *A descriptive Account of a new Method of treating old Ulcers of the Legs, edit.* 2, 1799.)

One circumstance, strongly in favour of the advantages of the foregoing mode of treatment, deserves particular notice: when M. Roux visited the London hospitals a few years ago, he had for the first time an opportunity of seeing this practice, which had never been tried in France. The plan appeared to him so different from every thing which he had been accustomed to see in his own country, where ulcers were almost always treated by rest in a horizontal posture, and emollient applications, that he left London somewhat prejudiced against the new method. Subsequently to his return to Paris, however, he has given it a fair trial, and experience has now entirely changed his opinion, as he has had the candour to acknowledge.—(See *Rélation d'un Voyage fait à Londres en* 1814; *ou Parallèle de la Chirurgie Angloise avec la Chirurgie Francoise, par P. J. Roux, p.* 150.)

OF ULCERS ATTENDED WITH SOME SPECIFIC DISEASED ACTION, EITHER CONSTITUTIONAL OR LOCAL.

1. *Ulcers which yield to Mercury.*

Here we shall exclude from consideration venereal ulcers, as this subject is treated of in the article *Vene-*

real Disease. At present we shall only notice such sores as are produced by other diseases of the general system, or of the parts, and are capable of being cured by mercury.

Perhaps there is no greater source of error in the whole practice of surgery, than the supposition that a sore, when it yields to mercury, must be of a syphilitic nature. Surgeons, however, who run into this absurdity, can hardly be imagined to be unaware, that so potent a medicine must have effects on numerous diseases of very different descriptions. Sir E. Home accurately remarks, that many ulcers, unconnected with the venereal disease, which receive no benefit from other medicines, heal under a mercurial course, or yield to mercurial applications. In some cases, the ulcer remains in the same state while mercury is used; but begins to look better as soon as the medicine is discontinued, in consequence of the beneficial change produced in the system by the mercurial course. In these cases, mercurial frictions are the best, because they occasion least impairment of the constitution, in consequence of the stomach continuing undisturbed, and capable of digesting well.

Another description of ulcers, noticed by Sir E. Home, as deriving benefit from mercury, occur on the instep and foot, have a very thickened edge, and are attended with a diseased state of the surrounding skin, so as to bear some resemblance to elephantiasis. They are frequently observed affecting servants who live in opulent families, in an indolent and luxurious way. Sir. E. Home states, that fumigations with hydrargyrus sulphuratus ruber heal these ulcers, and resolve in a great degree the swelling of the surrounding parts. In some instances, an ointment of calomel and hog's lard; in others, the camphorated weak mercurial ointment is the best application.

Many diseased ulcers, particularly those of a superficial kind, with a thickened edge, may be healed, when they are dressed with a solution of one grain of the hydrargyrus muriatus, in an ounce of water, containing a little spirit.

2. *Ulcers curable by Hemlock.*

Sir E. Home places more reliance on hemlock as an external than an internal remedy for ulcers. The ulcers which usually receive benefit from hemlock applications, look like those of an irritable sort; but the surrounding parts are thickened, in consequence of some diseased action. Such sores occur near the ankle; which joint is at the same time enlarged. Sometimes, but not so often, they take place over the ligaments of the knee. On account of their situation, and the swelling of the joint, they may be suspected to be scrofulous, though they are more sensible than strumous ulcers usually are. The sores just described are rendered less painful, their diseased disposition is checked, and the swelling of the joint diminished, by hemlock. Several irritable scrofulous ulcers are also particularly benented by this medicine.

Sir E. Home gives the preference to hemlock poultices, unless their weight should be objectionable, in which case he advises lint to be dipped in a decoction of the herb, and put on the sore.

Sometimes an ointment is made with the inspissated juice or extract.

3. *Ulcers curable by Salt Water.*

Sir E. Home takes notice of other specific ulcers, which yield to this application, after resisting other remedies. Poultices made with sea-water, are often employed; but this gentleman seems to prefer keeping the part immersed in the water in a tepid state, about a quarter of an hour, twice a day.

When sea-water poultices bring out pimples, in cases of scrofulous ulcers on the legs and feet, Sir E. Home informs us, that this disagreeable circumstance may be obviated by diluting such water with an equal quantity of a decoction of poppies. After a time, the salt water may be tried by itself again. While each fresh poultice is preparing, the part should also be immersed in such water warmed.

When there is a tendency to anasarca, or when there is an unusual coldness in the limb, unattended with any propensity to mortification, tepid salt water may be used with infinite advantage.

4. *Ulcers curable by the Argentum Nitratum.*

Sir E. Home notices, under this head, an ulcer, which does not penetrate more deeply than the cutis; but spreads in all directions, producing ulceration on the surface of the skin, and often extending nearly through its whole thickness. The part first affected heals, while the skin beyond it is in a state of ulceration.

Of this description are, a leprous eruption, mostly seen in men impressed in Ireland, a disease of the skin induced by buboes, which have continued a great while after the venereal virus has been destroyed; and the ring-worm.

All these diseases are most easily cured by applying to them a solution of the argentum nitratum.

The leprous eruption is communicated by contact, and makes its appearance in the form of a bile. This is converted into an ulcer, which discharges a fetid fluid, by which the surrounding skin is excoriated, and the ulceration is extended over a large surface. The pain is most severe, and the discharge greatest, in hot weather. The parts first diseased heal, while others are becoming ulcerated, and the disease is always rendered worse by spirituous liquors, salt provisions, and catching cold.

Sir E. Home remarks, that the disease in the skin produced by the effects of very irritable buboes, in constitutions broken down by mercury, is attended with ulceration of a more violent, deep, and painful kind than the foregoing distemper. The progress of this disorder is, in other respects, very similar to that of the leprous eruption.

Although the ring-worm only occurs in the form of an ulcer in warm climates, a mild species of the affection takes place in summer-time in this country. It seems to be infectious; though it often occurs without infection. It commences with an efflorescence, which is attended with very trivial swelling, and spreads from a central point. The circumference of the efflorescence becomes raised into a welt, while the rest assumes a scurfy appearance. The welt becomes covered with a scab, which falls off and leaves an ulcerated ring, in general not more than a quarter of an inch wide. The outer margin of this ring continues to ulcerate, while the inner one heals, so that the circle becomes larger and larger. The discharge consists of a thin, acrid fluid, which seems to have a great share in making the disease spread.

For all the three preceding diseases, a solution of the argentum nitratum is strongly recommended by Sir E. Home.

5. *Ulcers which yield to Arsenic.*

The sores which come under the definition of *noli me tangere* or *lupus*, derive great benefit from this powerful remedy. Sir E. Home observes, that they are nearly allied to cancer, differing from it in not contaminating the neighbouring parts by absorption, and only spreading by immediate contact.

From some cases which fell under Sir E. Home's observation, he discovered that arsenic was not only efficacious as an external, but also as an internal remedy. I shall not unnecessarily enlarge upon this subject in the present place, as the reader may refer to the articles *Arsenic*, *Cancer*, *Lupus*, *Hospital Gangrene*, &c., for additional information relative to the uses of this mineral in the practice of surgery.

Sir E. Home is an advocate for its employment, both internally and externally, for ulcers of untoward appearance on the legs. The *fungated* ulcer is particularly pointed out by this gentleman as being benefited by arsenic. This ulcer occurs on the calf of the leg, and on the sole of the foot. From its surface, a fungus shoots out, which is entirely different from common granulations. The new-formed substance is radiated in its structure, the bottom of the ulcer being the central point, and the external surface, which is continually increasing, the circumference. The substance of this fungus is very tender, and readily bleeds. The first stage of the disease sometimes has the appearance of a scrofulous affection of the metatarsal bones; but the parts seem more enlarged, and when the skin ulcerates, a fungus shoots out and betrays the nature of the case.

One species of the fungated ulcer is capable of contaminating the lymphatic glands; the other is not so. The first is represented by Sir E. Home as being incurable by arsenic or any other known medicine.

The second yields to this remedy. Sir E. Home uses a saturated solution, made by boiling white arsenic in

water for several hours, in a sand heat. He gives from three to ten drops internally; and for outward use, dilutes a drachm with two pints of water, making it afterward gradually stronger and stronger till it is of double strength. The application may either be made in the form of a poultice, or of lint dipped in the lotion.

The best and safest preparation of arsenic, both for internal and external use, is the kali arsenicatum. The mode of employing it may be learned by turning to the articles *Arsenic*, *Cancer*, *Potassa*, *Lupus*, &c.

6. *Ulcers attended with Varicose Veins.*

A certain kind of ulcer is very apt to occur on the inside of the leg, and is equally difficult to cure, and liable to break out again. It has the look of a mild, indolent sore; but the branches and trunk of the vena saphena are enlarged, and this varix of the veins keeps the ulcer from healing. The sore is seldom deep, usually spreads along the surface, and has an oval shape, the ends of which are vertically situated. There is a pain affecting the limb rather deeply, extending up in the course of the veins, and exasperated by keeping the leg a long while in an erect posture.

This is a kind of ulcer which derives immense benefit from a tight roller, applied from the toes to the knee, although the direct operation of the pressure of the bandage on the sore is itself productive of no particular good.

Sir E. Home found, however, that many patients could not bear laced stockings, or tight bandages, and that others received no relief from them. He represents, that in consequence of the size of the vena saphena, and its numberless convolutions, the return of blood from the smaller branches is so impeded as to retard the circulation in the smaller arteries, and to interfere with their action in forming healthy granulations. The coats and valves of the veins also become thickened, so that the latter parts (the valves) do not do their office of supporting the weight of the column of blood.

These reflections induced him to think, that some benefit might be obtained from applying a ligature round the vena saphena where this vessel passes over the knee-joint, so as to take off a part of the pressure of the column of blood. The following way of performing the operation was recommended: "As the veins are only turgid in the erect posture, the operation should be performed while the patient is standing; and if placed upon a table, on which there is a chair, the back of the chair will serve him to rest upon; and he will have the knee-joint at a very convenient height for the surgeon. The leg to be operated upon must stand with the inner ankle facing the light, which will expose very advantageously the enlarged vena saphena passing over the knee-joint. While the patient is in this posture, if a fold of the skin, which is very loose at this part, is pinched up transversely, and kept in that position by the finger and thumb of the surgeon on one side, and of an assistant on the other, this fold may be divided by a pointed scalpel, pushed through with the back of the knife towards the limb to prevent the vein being wounded; much in the same way as the skin is divided in making an issue. This will expose the vein sufficiently: but there is commonly a thin membranous fascia confining it in its situation; and when that is met with, the vein had better be laterally disengaged by the point of the knife. This is most expeditiously done by laying hold of the fascia with a pair of dissecting forceps, and dividing it; for it is difficult to cut upon parts which give little resistance, and there is a risk of wounding the vein. After this, a silver crooked needle, with the point rounded off, will readily force its way through the cellular membrane connected with the vein, without any danger of wounding the vessel, and carry a ligature round it. This part, or, indeed, what may be considered as the whole of the operation being finished, the patient had better be put to bed, so as to allow the vein to be in its easiest state before the ligature is tied, and then a knot is to be made upon the vein; this gives some pain; but it is by no means severe. The edges of the wound in the skin are now to be brought together by sticking plaster, except where the ligature passes out, and a compress and bandage applied, so as to keep up a moderate degree of pressure on the veins, both above and below the part included in the ligature."—(*Home. On Ulcers*, p. 295 *ed.* 2

As a general practice, I never entertained any doubt about the preference which ought to be given to bandages. Indeed, the risk attending the plan of tying and dividing large veins has now been displayed in so many fatal examples, that I begin to think, that, in a few years more, such operations will only be mentioned as things which ought not to be done. Sir A. Cooper, indeed, has already entered his protest against them, and mentions several cases in which the experiment had a fatal result.—(*Lectures, &c. vol.* 1, *p.* 205.)

It appears that A. Paré proposed and performed an operation similar to that described by Sir E. Home.—(*The Works of A. Paré, translated by Johnson; folio*, *p.* 319.) An account of Mr. Brodie's operation for the cure of varicose veins, and some additional remarks on the treatment of ulcers accompanied with varices, will be found in a subsequent article. See *Varicose Veins*. A description of what has sometimes been called the *hospital sore*, is given under the head of *Hospital Gangrene*.

7. *Ulcers from irritation of the Nails.*

Sometimes portions of the nails grow against, or even into the flesh of the fingers or toes, a fungus arises there, and, notwithstanding the repeated application of caustic, the disease returns, and the patient continues in a state of considerable pain and seriously disabled. The treatment recommended by Sir A. Cooper consists in paring the nail till it is as thin as it can be made without the production of bleeding: its edge is then to be raised, and a small bit of lint placed between it and the sore. When, however, the irritation is so great, that even the application of lint cannot be endured, he slits up the nail and turns it back with forceps, or even removes it.—(*Lectures, &c. p.* 200, *vol.* 1.) A common plan is to apply Plunket's caustic, a strong solution of nitrate of silver, the liquor arsenicalis, or a blister, so as to produce a separation of the offending part of the nail; but such treatment is sometimes tedious. According to Mr. Wardrop, the shape of the nail is not really altered, and the chief point in the treatment is, not to cut away any of it, but to reduce the swelling of the soft parts which press against the nail, and he has generally found that the application of lunar caustic destroys the painful and irritable ulcerated surface, while it promotes the absorption of the thickened parts.—(See *Med. Chir. Trans. vol.* 5, *p.* 131, *&c.*)

I shall conclude this article with a brief notice of Mr. Stafford's new method of treating deep excavated ulcers. It consists in pouring into the excavation melted wax of an extremely adhesive quality, and just of that temperature which it has when it is on the point of cooling, and when it will immediately become solid in the ulcer. In this manner the under surface of the wax, when cold, comes into close contact with the general surface of the sore, and the whole excavation is filled by it. The ulcer having been cleaned with dry lint, a brush is then to be dipped in the melted wax, which is to be allowed to drop from it into the sore. After the wax has become solid, it is to be retained in its place with a strip or two of adhesive plaster. This mode of dressing is to be renewed on the third day. The presence of the mass of wax seems to have the effect of exciting the growth of healthy granulations. The wax used by Mr. Stafford consists of four parts of white wax, and of one of Venice turpentine. The cases to which he conceives this treatment adapted are, "the open and excavated bubo; ulcers of the legs; indolent scrofulous sores; excavations in the flesh in consequence of sloughing phagedœna; ulcers situated over large arteries; sinuses and fistulous passages that have been laid open; the sores left by extensive burns; broken chilblains; and, in short, those of any depth, from whatever cause they may arise." He also speaks of its utility in cancerous ulcers.—(See *Stafford's Essay upon the Treatment of the Deep and Excavated Ulcer*, 8*vo. Lond.* 1829.) As I have never tried this simple method, it is impossible for me to offer any positive opinion on its merits. Mr. Stafford's accounts of it are very flattering; and it is to be hoped that other practitioners may find it as efficacious as he seems to have done in so many ulcers, and these of characters so very different.

Essay upon the Treatment of the Deep and Excavated Ulcer, by R. A. Stafford,* 8vo. *Lond.* 1829.

UNGUENTUM ACIDI SULPHURICI.—℞. Acidi Sulphurici ʒ j. Adipis Suillæ præparatæ ℥ j.—These are to be well mixed together in a glass mortar.

This ointment has been used by Dr. Duncan, of Edinburgh, for curing the itch. It has the character also of being efficacious in the reduction of some chronic swellings of the joints; and when mixed with a good deal of camphor, it was rubbed upon the tumour in cases of bronchocele, by Mr. Naylor, of Gloucester, with considerable effect.

As the sulphuric acid is particularly destructive of vegetable substances, the parts to which this ointment is applied, should always be covered with flannel instead of linen.

UNGUENTUM ANTIMONII TARTARIZATI.—℞. Antim. Tart. ʒ j. Ung. Cetacei ℥ j. Misce. The antimonial ointment, frequently used for exciting irritation of the skin, with the view of relieving diseases in the vicinity of the irritated part, as is exemplified in the treatment of some diseases of the eyes and joints, and a variety of indolent swellings.

UNGUENTUM CETACEI.—℞. Cetacei ʒ vj. Ceræ Albæ ʒ ij. Olei, Olivæ uncias tres. These are to be melted upon a slow fire, and then briskly stirred till cold.—This ointment, spread on lint, serves as a simple dressing for wounds, ulcers, &c.

UNGUENTUM CERÆ CUM ACETO.—℞. Ceræ Albæ ℥ iv. Olei Olivæ ℔j. Aceti Distillati ℥ ij. The vinegar is to be gradually mixed with the first two ingredients after these have been melted together. Dr. Cheston recommends this ointment for superficial excoriations, cutaneous eruptions, &c.

UNGUENTUM CONII.—℞. Foliorum Conii recentium. Adipis Suillæ præparatæ, sing. ℥ iv. The hemlock is to be bruised in a marble mortar, after which the lard is to be added, and the two ingredients thoroughly incorporated by beating. They are then to be gently melted over the fire, and after being strained through a cloth, and the fibrous part of the hemlock well pressed, the ointment is to be stirred till quite cold. To cancerous or scrofulous sores this ointment may be applied with a prospect of advantage.—(*Pharm. Chirurg.*)

The Pharmacopœia of St. Bartholomew's Hospital directs the unguentum conii, vel cicutæ, to be made as follows:—℞. Foliorum Cicutæ ℔j. Adipis Suillæ ℔iss. Boil the leaves in the melted hog's lard until they become crisp. Then strain the ointment. A similar ointment might be more conveniently made, by mixing the extractum conii with any common salve.

UNGUENTUM DIGITALIS.—℞. Foliorum Digitalis Purpureæ recentium. Adipis Suillæ preparatæ, sing. ℥ iv. This ointment may be made in the same manner as the unguentum conii, and tried in the same cases.

UNGUENTUM ELEMI COMPOSITUM.——℞. Elemi ℔j. Terebinthinæ ʒ xi. Sevi Ovilli præparati ℔ij. Olei Olivæ ʒ ij. Melt the elemi with the suet; remove them from the fire, and mix them immediately with the turpentine and oil. Then strain the mixture.—Sometimes employed for dressing ulcers which stand in need of stimulating applications.

UNGUENTUM GALLÆ CAMPHORATUM —℞. Gallarum Pulveris Subtilissimi ʒ ij. Camphoræ ʒ ss. Adipis Suillæ preparatæ ℥ ij. Misce.—This is a very good application to piles, after their inflammatory state has been diminished by the liq. plumbi acet. dilut., bleeding, aperient medicines, and leeches.

UNGUENTUM HELLEBORI ALBI.—℞. Hellebori Albi Pulv. ℥ j. Adipis Suillæ præparatæ ℥ iv. Olei Limonis ♋ss. Misce.—This ointment will cure the itch, and several other cutaneous diseases.

UNGUENTUM HYDRARGYRI FORTIUS.—℞. Hydrargyri purificati ℔ij. Adipis Suillæ preparatæ ℥ xxiij. Sevi Ovilli præparati ℥ j. First rub the quicksilver with the suet, and a little of the hog's lard, until the globules disappear; then add the remainder of the lard, and make an ointment.—This is the common strong mercurial ointment. Of its uses we need say nothing in this place. See *Mercury.*

UNGUENTUM HYDRARGYRI CAMPHORATUM.—℞. Unguenti Hydrargyri ℥ j. Camphoræ ʒ ss. Misce.—This is often recommended to be rubbed on thickened, indurated parts, with the view of exciting the action of the absorbents. Rubbed along the course of the urethra, it is very serviceable in diminishing and removing chordee.

UNGUENTUM HYDRARGYRI MITIUS.—℞. Unguenti Hydrargyri fort. ℔j. Adipis Suillæ præparatæ ℔ij. Misce.—The weaker mercurial ointment is often rubbed on indurated, thickened parts and tumours, when the object is merely to promote their absorption; and it is not advisable to employ the unguentum hydrargyri fort. lest a salivation should be induced.

UNGUENTUM HYDRARGYRI NITRATIS.—℞. Hydrarg. Purificati ℥ j. Acidi Nitrosi ℥ ij. Adipis præparatæ ℥ vj. Olei Olivæ ℥ iv. Dissolve the quicksilver in the nitrous acid; and while the solution is yet hot, mix with it the oil and hog's lard, previously melted, but beginning to concrete by being exposed to the air. This ointment is a celebrated application to the inside of the eyelids in cases of chronic ophthalmy, and also to specks on the cornea. When blended with a little olive oil, it also forms a very eligible stimulating dressing for numerous kinds of sores. It is particularly efficacious in curing tinea capitis and many other cutaneous diseases.

UNGUENTUM HYDRARGYRI NITRICO-OXYDI.—℞. Hydrargyri nitrico-oxydi ℥ j. Ceræ Albæ ℥ ij. Adipis præpar. ℥ vj. Misce.—This is a common stimulating application to indolent ulcers and sores in general.

UNGUENTUM HYDRARGYRI PRÆCIPITATI ALBI.—℞. Hydrarg. Præcip. Albi ʒ j. Adipis præparatæ ℥ iss. Misce. A useful application in certain cases of porrigo, and some other cutaneous diseases. See *Porrigo.*

[There is scarcely to be found among the whole class of unguents so valuable a means of relief as that which is afforded by the white precipitate ointment in cases of venereal ulcers. The formula may be ung. simpl. ℥ j. cum præcip. alb. ʒ ij. M. The dressings may be renewed two or three times a day. The excess of discharge created is no less remarkable than the alteration effected in the part itself. I have more freely applied this unguent to venereal ulcers in different parts of the body than any other prescription; when the disease has been of comparatively short existence, and when the constitution has laboured under the infirmity for months and even years.—*Reese.*]

UNGUENTUM IODINÆ. See *Iodine.*

UNGUENTUM LIQ. PLUMBI ACETATIS.—℞. Liquoris Plumbi Acetatis ℥ v. Adipis Suillæ ℔j. Ceræ Albæ ℥ iv. Melt the ingredients together, and continue to stir them till cold.—This ointment is employed with great advantage as a simple dressing. According to Mr. Dunn, of Scarborough, it is much improved by pouring the liquefied mixture before the lead has been added to it into cold water. It is then to be rubbed in a mortar or on a slab, with the liq. plumbi acet. The water occasions a fine white cloudy precipitation, which gives to the composition a better appearance.

UNGUENTUM OPHTHALMICUM —℞. Adipis

Suillæ preparatæ ʒss. Tutiæ præparatæ, Bol. Armen. sing. ʒij. Præcip. Hydrarg. Albi. ʒj. Misce.—Janin's celebrated ophthalmic ointment.

UNGUENTUM OXYGENATUM, vel ACIDI NITROSI.—℞. Axungiæ Suillæ recentis non salsæ uncias octodecim. Leni calore in vase vitreo lente liquefactis aut continua agitatione instillentur Acidi Nitrici unciæ duæ. Massa igni exponatur, donec ebullire cœpit; tunc ab igne removeatur, frigefactaque sevetur.

In this process the nitric acid is decomposed, the nitrous gas escaping, and the oxygen combining with the lard. This ointment was particularly recommended by Alyen, as an application to venereal and herpetic ulcers. Its virtues are said to vary considerably, according to the strength of the acid employed, and it is not generally deemed so efficacious as the ointment of nitrate of mercury.

UNGUENTUM PICIS.—℞. Picis, Sevi Ovilli præparati, sing. ℔ss. Melt and then strain them.

UNGUENTUM PICIS COMPOSITUM.—℞. Unguenti Picis, Unguenti Plumbi Superacetatis sing. ℔ss. Misce.

The two preceding ointments are applicable to cases of tinea capitis, and some eruptive complaints. Also to some kinds of irritable ulcers.

UNGUENTUM PICIS CUM SULPHURE.—℞. Unguenti Picis, Unguenti Sulphuris, sing. ʒiv. Misce. —This is one of the most common, and, I believe, the most efficacious applications for curing porrigo.

UNGUENTUM PLUMBI SUPERACETATIS.—℞. Plumbi Superacetatis ʒij. Ceræ Albæ ʒij. Olei ℔ss. The superacetate of lead, previously powdered, is to be triturated with part of the olive oil. The melted wax and rest of the oil are then to be added. This is a good dressing for cases requiring a mild astringent application.

UNGUENTUM RESINÆ.—℞. Resinæ Flavæ, Ceræ Flavæ sing. ℔j. Olei Olivæ ℔j. Melt the resin and wax with a slow fire; then add the oil, and strain the mixture while hot.—This is a common application to ulcers which stand in need of being gently stimulated.

UNGUENTUM SAMBUCI.—℞. Florum Sambuci, Adipis Suillæ, singulorum ℔j. The hog's lard being melted, boil the elder flowers in it till they become crisp, then strain the mixture.

UNGUENTUM SULPHURIS.—℞. Adipis Suillæ ℔ss. Florum Sulphuris ʒiv. Misce.

UNGUENTUM TUTIÆ.—℞. Tutiæ præparatæ, Unguenti Cetacei q. s. Misce.—Used for smearing the borders and inside of the eyelids in cases of chronic ophthalmy, &c.

UNGUENTUM TUTIÆ COMPOSITUM.——℞. Tutiæ præparatæ, Lapidis Calaminaris præparati, sing. ʒvj. Camphoræ ʒij. Unguenti Sambuci ℔j. Misce.

This formula is contained in the Pharmacopœia of St. Bartholomew's Hospital. It is occasionally applied to the inside of the eyelids, piles, ulcerations, excoriations, &c.

UNGUENTUM ZINCI.—℞. Zinci oxydi ʒj. Adipis præpar. ʒvj. Misce.—An astringent application in very common use.

UNGUIS. (*A nail.*) Some surgical authors apply this term to a collection of pus, or matter in the eye, when the abscess appears, through the cornea, to be shaped like a finger nail.

UNION BY THE FIRST INTENTION.—When the opposite surfaces of a wound are brought into contact and grow together at once without suppurating, union by the first intention is said to take place. When wounds heal by suppurating, granulating, &c. they are sometimes surgically described as getting well by the second intention. *See Wounds.*

URETHRA, DESTRUCTION OF PART OF THE. —The attempts to complete the canal by operations performed on the Tallacotian principles, will be noticed in the article *Urinary Fistula.*

URETHRA, STRICTURES OF.—A stricture of the urethra, as a modern writer observes, "consists of some morbid alteration of action or of structure, by which a part of the canal is rendered narrower than the rest."—(*Wilson on the Male Urinary and Genital Organs, p.* 361.) According to Mr. John Hunter, most obstructions to the passage of the urine, if not all, are attended with nearly the same symptoms. Few persons take notice of the first symptoms of a stricture, till they have either become violent, or other inconveniences have been the consequence. A patient may have a considerable stricture, yet be unconscious that his urine does not come away freely; and, in consequence of a stricture, there may even be a tendency to inflammation and suppuration in the perinæum, while he feels no obstruction to the passage of his urine, and does not suspect that he has any other complaint.

Three kinds of strictures are described; viz. the *permanent* stricture, which arises from an alteration in the structure of the part of the urethra; the *mixed*, consisting of a permanent stricture and a spasm; and the *spasmodic.*

It is observed by a modern writer, that the spasmodic stricture arises from the whole or a part of the canal of the urethra being so highly irritable, that the slightest stimulus will cause it to contract and occasion the stream of urine to be suddenly obstructed. Spasmodic strictures he considers as being often the result of faulty digestion. He has known a spasmodic stricture follow the eating of high-seasoned and indigestible food, or the drinking of acidulous liquors; and he asserts, that the spasmodic state of the urethra will cease if the irritating substance in the alimentary canal be carried off, or the acid neutralized. When general irritability exists, he believes that spasmodic affection of the urethra may be brought on by urine of an irritating quality, or any other local stimulation of the urethra, as by a bougie, &c.—(See *Stafford on Strictures in the Urethra, &c. p.* 3.)

Whether the urethra be a truly muscular canal, and whether a variety of circumstances, remarkable in its healthy and diseased state, can be accounted for by its elasticity, the action of the muscles in the perinæum, and other principles, without supposing the canal to be itself muscular, are questions on which different opinions are entertained. However, the generality of modern practitioners in this country incline to that view of the subject which refers the property of muscularity either to the membrane of the urethra itself, or to the substance immediately surrounding it. The latter has been alleged to be the real case. "From Mr. Bauer's examination (says Sir Everard Home) we find that the human urethra is made up of two parts, an internal membrane, and an external muscular covering. The internal membrane is exceedingly thin, and no fibres are met with that can give it the power of contraction. When it is put on the stretch in a transverse direction, the circumference of the canal is no ways increased; but when stretched longitudinally, a small degree of elongation is produced. When a transverse section of the urethra is made, while in a collapsed state, the internal membrane is found thrown into folds, pressed together by the surrounding parts." It is afterward explained, that "the muscular covering by which the membrane is surrounded, or enclosed, is made up of fasciculi of very short fibres, which appear to be interwoven together and to be connected by their origins and insertions with one another. *They all have a longitudinal direction.* There is a greater thickness of this muscular structure upon the upper than the under surface of the urethra, which is still more evident as it approaches nearer to the external orifice. The fasciculi are united together by an elastic substance of the consistence of mucus. Immediately beyond the muscular portion of the urethra, is the cellular structure of the corpus spongiosum."

Formerly, "it was believed, that either the lining of the urethra was composed of *circular* fibres, possessed of a power of contraction, or that it was immediately surrounded by such fibres; and, therefore, that the disease commonly known by the name of a stricture in the urethra was produced by a contraction of some of these *circular* fibres; and that permanent stricture was a term applied to these parts, when, in consequence of inflammation, they became confined to that particular state. We now find that *the lining of the urethra is never met with in a contracted state*, but is thrown into folds by the action of the elastic ligamentous covering of the corpus spongiosum, and the swell of the *longitudinal* muscular fibres within it; and when these fibres have, by acting through their whole length, reduced the urethra to its shortest state, the pressure upon the internal membrane is so great that there is not room for the urine to pass, till these fibres are relaxed by elongating the whole canal.

A *spasmodic stricture* is in reality *a contraction of a small portion of the longitudinal muscular fibres*, while the rest are relaxed; and as this may take place either all around, or upon any one side, it explains what is met with in practice, and could not before be satisfactorily accounted for; the mark, or impression of a stricture sometimes forming a circular depression upon the bougie; at other times, only on one side.

A *permanent stricture* is *that contraction of the canal which takes place in consequence of coagulable lymph being exuded between the fasciculi of muscular fibres, and upon the internal membrane*, in different quantities, according to circumstances: and, in the same proportion, diminishing the passage for the urine at that part, or completely closing it up."—(*Sir Everard Home in Phil. Trans.* 1820, *and Pract. Obs. on Strictures, vol.* 3, *p.* 26, *&c.* 8*vo. Lond.* 1821.)

For a particular detail of the arguments and remarks urged against the doctrine of the urethra being a tube, capable of having its diameter suddenly lessened at every point by the contraction of muscular fibres, I must refer to the writings of Mr. C. Bell and Mr. Shaw, whose statements, indeed, have been noticed in my introductory work.—(See *First Lines of the Practice of Surgery*, *p.* 595, *ed.* 5.)

In all obstructions of the urethra, the stream of water becomes small in proportion to the stoppage; but though this symptom is probably the first, it is not always observed by the patient.

According to Sir A. Cooper, the earliest symptom of a stricture is the retention of a few drops of urine in the urethra, after the patient has made water, which drops soon escape, and slightly wet the linen, while another small quantity of urine collected between the neck of the bladder and the stricture, may be expelled by pressure on the lower side of the urethra. This inability of completely emptying the urethra, however, is observed in the generality of persons after a certain age, and even in youngish individuals who have led irregular lives: much stress, therefore, cannot be laid upon this circumstance alone. The next thing noticed, he says, is an irritable state of the bladder, evinced by the patient not being able to sleep so long as usual, without discharging his urine. As the disease increases, the stream of urine is forked, spiral, or scattered; and, in a more advanced stage, the water is often voided only by drops, especially when the urethra is under the influence of cold, irritation, or the effects of intemperance. When the stream of urine is thus altered, or broken, Mr. Hunter recommends the passage to be examined with a bougie; and, and if one of a common size can be readily introduced, the difficulty of voiding the urine is likely to depend on a diseased enlargement of the prostate gland, which should be examined.—(See *Prostate Gland.*)

The spasmodic stricture may be known by its being only of temporary duration. This kind of case, and more particularly the permanent stricture, are generally attended with a gleet. The latter complaint is often suspected to be the only one, until all efforts to produce a cure are found to be fruitless.

In diseases of the urethra, and also of the prostate gland and bladder, there is commonly an uneasiness about the perinæum, anus, and lower part of the abdomen.—(*Hunter.*)

The first progress of the contraction is generally very slow; but when once it has so far increased, that the longitudinal fibres are not wholly relaxed by the force of the urine, its subsequent advances are more rapid, and new symptoms are perceived. The urine is voided more frequently, does not pass without a considerable effort, attended with pain; and a straining sensation continues after the bladder is emptied. If the patient accidentally catch cold, drink a glass of spirituous liquor, acid beverage, or punch, commit an excess in drinking wine, or remove quickly from a warm to a cold temperature, the urine will, perhaps, pass only in drops, or be entirely obstructed. These causes induce, in the longitudinal fibres at the contracted part, a spasmodic action by which it is closed. Cold, externally applied to the body, has so great an effect upon a spasmodic stricture, that a patient, who can make water without the smallest difficulty in a warm room, is often quite unable to void a drop, on making the attempt in the open air. However, on returning to a warm room, and sitting down a little while, he becomes able again to expel his urine. The symptoms of a stricture are more frequent in persons who lead a sedentary life than in others whose pursuits are active.

Strictures in the urethra being attended with a discharge and pain in making water, especially after any excess, are frequently regarded and treated as a gonorrhœa. These two symptoms often come on a few hours after connexion with women; the degree of inflammation is very slight; the discharge is the first symptom, and is more violent at the commencement than at any other period. The inflammation subsides in a few days, leaving only the discharge, which also frequently disappears in five or six days, whether any means be employed or not for its removal.—(*Home.*)

What renders a stricture particularly apt to be mistaken for a gonorrhœa is, that in both diseases, the pain in making water is experienced about an inch and a half from the orifice of the glans penis.

In consequence of the natural sympathy between the urethra and testicles, the latter organs are apt to swell in cases of stricture; and as there is also a discharge, the disease is often mistaken for a common hernia humoralis from gonorrhœa, and a treatment on very wrong principles is instituted.

In a more advanced stage, the part of the urethra, which is the seat of stricture, is always much narrower than the rest of the canal. The stricture is permanent, being combined with a thickening of structure, whereby the diameter of the diseased part of the passage is lessened. However, the diameter of the affected portion of the canal even now varies, according as the spasm and projection of the longitudinal fibres, and the spasmodic action of the muscles about the perinæum, and the effects of inflammation, contribute more or less to a temporary increase of the obstruction. In the language of Sir Everard Home, the case is now both a permanent stricture and a spasmodic one; permanent, because the diseased part of the urethra is always narrower than the rest of this passage; and spasmodic, inasmuch as the stricture may be rendered still more contracted by spasm affecting the muscular structure, adjoining the disease. In the contracted state, the passage is closed up; in the relaxed, the urine can pass through it in a small stream.

In old cases of stricture, the muscular coat of the bladder becomes thickened and stronger than natural, in consequence of more force being necessary to propel the urine through the obstructed part. The bladder, in this thickened state, does not admit of the usual dilatation, so that the patient is obliged to make water very frequently, and he is unable to pass the whole night without making this evacuation once or twice.—(*Home.*)

A nocturnal emission of the semen is another very common symptom of a stricture; and some patients seem to have no other complaint attendant on the disease of the urethra.

A periodical discharge is sometimes brought on by cold, or other occasional causes. When the inflammation extends to the bladder, the frequency of making water is considerably increased, and the urine very turbid. It is voided for twelve or twenty-four hours, once or even twice every hour; and, when allowed to stand, it deposites a substance in the form of powder, consisting of coagulable lymph. This is the slightest kind of attack.

Sometimes the bladder is inflamed in a greater degree, and secretes pus, which is discharged with the urine. In a still more violent attack, the discharge is similar to the white of an egg, and particularly adhesive, being, according to Sir Everard Home, the vitiated secretion of the prostate gland. When the inflammation of the bladder becomes still worse, the affection sometimes extends to the peritoneum, and the patient dies.

As strictures of long standing always impede the passage of the urine, the bladder acts with augmented force to overcome the resistance. In this manner, the stricture is kept in a continual state of irritation, and the obstruction becomes more and more considerable.

In a few cases, indeed, the diseased part of the urethra is rendered quite impervious; and the patient's life is preserved by the urethra ulcerating at some point within the obstruction, and fistulous openings taking place in the perinæum.—(See *Fistulæ in Perinæo.*)

As Sir A. Cooper has correctly observed, piles are sometimes a consequence of strictures; and the efforts

made to expel the urine, are occasionally a cause of the direct or internal inguinal hernia.

Strictures are frequently attended with constitutional symptoms, one of which is a complete paroxysm of fever. The cold fit is very severe; this is followed by a hot fit, and then a profuse perspiration. During the rigor nausea and vomiting generally occur, and at this period the patient has occasion to make water frequently, seldom experiencing at the same time any strangury. When the fit is tolerably complete, the patient suffers in general only one; in the opposite circumstance two; but a greater number rarely happens. Such febrile paroxysms are most frequent in warm countries; but do every now and then take place in this climate, particularly in consequence of exposure to cold, excesses, and the introduction both of common and armed bougies. They are also said, by Sir A. Cooper, to be common in that stage of the disease in which the urine is blended with pus.

According to the principles of Sir Everard Home, the longitudinal muscular fibres on the outside of the membrane of the urethra are liable to a spasmodic contraction, in which state their swell lessens the diameter of the passage, and they are incapable of becoming relaxed again until the spasm is removed. This spasmodic stricture is only a wrong action of these longitudinal fibres; and, if the parts could be examined in their relaxed state, there would be no appearance of disease.

When the contraction is not considerable, it appears, on examination after death, to be merely a narrowing of the urethra; but a permanent stricture, in a more advanced state, usually consists of a ridge, which forms a projection in the passage.—(*Home.*) The latter form of the disease is now described by the generality of modern writers as the effect of chronic inflammation.—(*C. Bell, Boyer, Sir A. Cooper, &c.*)

Mr. Hunter informs us, that the disease generally occupies no great length of the passage; at least, that this was the case in most of the instances which he examined. In these cases, the contraction was not broader than if it had been produced by surrounding the urethra with a piece of packthread; and in many it had a good deal of the appearance which one may fancy such a cause would produce. He had seen, however, the urethra contracted for more than an inch in length, owing to its coats or internal membrane being irregularly thickened, and forming a winding canal. I lately saw a man in the King's Bench prison, whose urethra was completely obliterated from the glans to the perinæum, where a fistula was situated, out of which he voided his urine. Besides these forms of stricture, Sir A. Cooper used to show in his lectures a kind of stricture produced by the extension of a membranous band across the passage.

According to Mr. Stafford, the contractions which occupy a considerable extent of the passage are generally extremely irregular; and their structure resembles that of cartilage, being indurated and tough. In these cases, which are usually of long standing, the membrane likewise partakes of the change, being firmer and thicker than natural.—(*On Strictures, &c. p.* 11.)

A stricture does not always arise from an equal contraction of the urethra all round; for in some instances, the contraction is only on one side; a fact which appears to me to be better accounted for by the consideration of the longitudinal arrangement of the muscular fibres in packets on the outside of the membrane of the urethra, than the circular kind of stricture only occupying as small an extent of the passage as the constriction which would arise from the application of a piece of packthread round it. The contraction of one side of the canal only throws the passage to the opposite side, which often renders the introduction of a bougie difficult. The contracted part is whiter than the rest of the urethra, and is harder in its consistence. In some cases there are several strictures. Mr. Hunter saw half a dozen in one urethra, and he observes, that a stricture is frequently attended with small tightnesses in other parts of the passage. According to the same authority, every part of the urethra is not equally subject to strictures, the bulbous portion being much the most subject to them. A stricture is sometimes situated on this side of the bulb, *but very seldom beyond it*, that is, *nearer the bladder*. Mr. Hunter never saw a stricture in that part of the urethra which passes through the prostate gland; and the bulb, besides being the most frequent seat of this disease, is also subject to it in its worst forms.

Sir Everard Home measured the length of the urethra in different subjects, and examined the diameters of the several parts of the passage. Strictures, according to this gentleman, *occur most commonly just behind the bulb* of the urethra, the distance from the external orifice being 6½ or 7 inches. The situation next in the order of frequency is about 4½ inches from the orifice of the glans. The disease does also occur at 3½ inches, and sometimes almost close to the external orifice. The two parts of the urethra most frequently affected with strictures are naturally the narrowest. Sometimes the very orifice of the urethra is contracted, and the circumstance often leads to an erroneous supposition, that the whole canal is naturally formed of the same size. In cases of strictures the prepuce also is observed to be particularly often affected with a natural phymosis.

In almost all the cases which Sir E. Home met with there was one stricture about seven inches from the external orifice, whether there were any others or not.

We have seen that Mr. Hunter and Sir E. Home do not agree respecting the most frequent place of strictures. Sir A. Cooper also partly differs from both these authorities; for, though he coincides with Mr. Hunter, in setting down the most common situation to be in front of the bulb, just where this part joins the corpus spongiosum, yet he varies from both in representing strictures in the membranous and prostatic portions of the urethra as next in order of frequency. Here, however, he may comprehend the variations in the course of the urethra, and the obstruction to the passage of the urine attending disease of the prostate gland; cases generally considered as a separate subject.

Among the consequences of the disease which are found on dissection are, first, in very bad cases, a great dilatation of the urethra behind the stricture; secondly, a considerable thickening of the coats of the bladder, as already mentioned; thirdly, enlargement of the ureters, an effect of their being distended with urine during the retentions common in the advanced stages of the disease; fourthly, the kidneys are often diseased, their glandular structure being sometimes entirely destroyed, and the rest of them enormously dilated; a mode in which the case may prove fatal. The prostate gland is frequently enlarged; abscesses are occasionally found in it, with fistulæ leading from them to the perinæum or parts around, and its natural ducts are often considerably dilated.—(See *Stafford on Strictures, &c. p.* 41, *ed.* 2.)

The portion of the urethra between the stricture and the bladder is generally more or less inflamed; and ulceration of it much disposed to take place, and to lead to abscesses and fistulæ in the perinæum.

With respect to the causes of strictures, some writers have imputed the disorder to the effects of gonorrhœa, and often to the method of cure. Mr. Hunter entertained strong doubts, however, whether strictures commonly or ever proceeded from those causes; though he acknowledges, that since most men have had gonorrhœa, a refutation of the opinion is very difficult. He was led to think, that strictures did not commonly arise from such causes, by reflecting that they are common to most passages in the human body. They often take place in the œsophagus; the intestines, particularly the rectum; the anus; the prepuce, so as to produce phymosis; and in the lachrymal duct, so as to occasion a fistula lachrymalis. Strictures sometimes take place when there have been no previous venereal complaints. Mr. Hunter saw an instance of this kind in a young man, nineteen years of age, who had had the complaint for eight years, and which therefore began when he was only eleven years old. He was of a weak scrofulous habit. Mr. Hunter had also seen a stricture in a boy only four years old, and a fistula in perinæo in consequence of it. Strictures, he says, happen as frequently in persons who have had gonorrhœa in a slight degree as in others who have had it in a severe form.

However, it must not be dissembled, that many very judicious and experienced men still regard Mr. Hunter's conclusions on this question as erroneous, and Sir A. Cooper in particular differs from him so much as to say, that he considers gonorrhœa in ninety-nine cases out of a hundred to be the cause of strictures. At the same time, he admits the possibility of their origin

from other causes, and mentions a case which he saw himself, and which arose from an injury received by a child as it was riding on horseback. Delpech also describes strictures as a very frequent consequence of gonorrhœa; and he is a zealous advocate for cubebs and copaiba in this last disorder, because his observations lead him to believe, that, by shortening its duration, they materially lessen the chance of strictures.—(*Clinique de Chir. p.* 271.)

It is not an uncommon belief, that strictures arise from the use of astringent injections in the treatment of the gonorrhœa. Sir Everard Home is of this sentiment, and so was the late Mr. Wilson.—(*On the Male Genital and Urinary Organs, p.* 370.) The latter gentleman, however, mentions some circumstances calculated to raise doubts on this point, especially the fact, that while injections rarely enter far into the urethra, the most common seat of a stricture is where the membranous part of the canal joins the bulb. Mr. Hunter himself deemed the opinion founded on prejudice, and states that he had seen as many strictures after gonorrhœa, which had been cured without injections, as after cases which had been treated with these latter applications.

He rejected also the old doctrine, that strictures are a consequence of ulcers in the urethra; for, ulcers hardly ever occur in this passage, except when there are strictures; and it is now generally admitted, that in gonorrhœa there are no sores in the urethra. Strictures are sometimes produced by external violence, though the passage would appear to be capable of frequently bearing considerable wounds and other injuries without this consequence. Thus, strictures are not common from lithotomy, and in a modern work we read the case of a serious gun-shot wound of the urethra, where no stricture ensued.—(See *Annuaire Méd. Chir. des Hôpitaux de Paris*, 4*to.* 1819.)

According to a well-informed modern writer, strictures are mostly preceded by a state of the passage, called an *irritable urethra*, which has great share in bringing them on. The morbid sensibility by which it is chiefly characterized may affect the whole passage, or only part of it, in which last case the prostatic portion is almost always that which is affected. In cases of irritable urethra, the size of the stream of urine varies remarkably at different times, the variation being, it is said, much greater than in examples of stricture.—(See *Macilwain's Treatise, p.* 9, *&c.*) There can be no doubt that what this gentleman has so well described as the *irritable urethra*, is the same case which some other writers denominate *spasmodic stricture.*

SPASMODIC STRICTURES, OR IRRITABLE URETHRA.

These cases should be treated by removing the cause, and, if they depend upon disordered digestion, as is sometimes alleged, whatever gives rise to this state must be avoided or removed. If, says Mr. Stafford, the spasmodic stricture depend upon the extreme irritability of the urethra, occasioned by a morbid irritability of the stomach, and produced by some irritating cause in that organ, we should remove the offending matter, or neutralize its effects; we may also exhibit opium, camphor, and other antispasmodics, or employ fomentations. If the urine be of too stimulating a quality, mucilaginous drinks and alkalies may be prescribed. The diet should be plain, and medicines given to promote digestion and the excretions. Whenever the evacuation of urine is attended with much pain, spasm, and a diminution of the stream, leeches should be applied to the perinæum, the patient put into the warm bath, and aperients given. These remedies are to be repeated at least twice a week or oftener, according to circumstances. When the pain and irritation in the urethra have subsided, and not sooner, a bougie may be introduced to ascertain the state of the passage. If the instrument give much pain, and be quite resisted by spasm, it is to be concluded, that the inflammation of the urethra is not subdued, and the antiphlogistic soothing means, leeches, low diet, fomentations, opium, hyosciamus, conium, subcarbonate of potash, oplate clysters, and purgative medicines, must be continued. Afterward, that is to say, when the inflammation has been quite subdued, the morbid irritability of the urethra may be removed by the gentle and occasional employment of bougies or catheters.—(See *Stafford on Strictures, p.* 42, *&c.*)

TREATMENT OF STRICTURES WITH COMMON BOUGIES, ON THE PRINCIPLE OF DILATATION.

The cure of strictures may be accomplished either by a dilatation of the contracted part, or a destruction of it by ulceration or escharotics. To these methods are to be added, first, the plan of forcing a passage through the stricture with a conical sound, as practised by the French surgeons when they cannot otherwise get through the stricture, and the symptoms are urgent.—(See *J. Cross, Sketches of the Medical Schools of Paris*, 8*vo. Lond.* 1815, *p.* 111; *and First Lines of the Practice of Surgery, ed.* 5.) Secondly, the method of cutting down to obliterated portions of the urethra, and attempting to cure the obstruction by the removal of the diseased parts, tracing the continuation of the passage, and trying to heal the wound over a catheter. Both these practices are attended with such difficulties and dangers, as should make a prudent surgeon reluctant to adopt them, except under the most urgent circumstances, in which every milder method fails. Thirdly, the practice of perforating strictures with a sharp instrument introduced from the orifice of the urethra. The dilatation is accomplished by means of bougies, catheters, and dilators; but Mr. Hunter considered that a cure effected on this principle was seldom or never more than temporary. The removal of strictures by ulceration may also be effected with bougies; their destruction is accomplished with *caustic* or *armed bougies.*

The cure by dilatation is principally mechanical when effected by bougies, the powers of which are generally those of a wedge. However, Mr. Hunter conceived that their ultimate effect was not always so simple as that of a wedge upon inanimate matter; for pressure makes living parts either adapt themselves to their new position, or else recede by ulceration. Bougies, of course, either dilate strictures, or make them ulcerate.

The disease has generally made considerable progress before surgical assistance is required; and the stricture may be so advanced, that a small bougie cannot be made to pass without a great deal of trouble. If the end of a small bougie, let it be ever so small, can be introduced through the stricture, *the cure is then in our power.* However, a small bougie frequently cannot pass in the first instance, and even not after repeated trials.

Often when the stricture is very considerable, a great deal of trouble is given by occasional spasms, which either resist the introduction of a bougie altogether, or only allow a very small one to pass. At other periods, however, a larger one may be introduced. In these circumstances, Mr. Hunter sometimes made the point of the bougie enter, by rubbing the outside of the perinæum with the finger of one hand, while he pushed the bougie on with the other. He also frequently succeeded by letting the bougie remain a little while close to the stricture, and then pushing it on. Sometimes the spasm may be taken off by dipping the glans penis in cold water.

Although, in cases of permanent strictures, the bougie may not pass at first, yet, after repeated trials, it will every now and then find its way. In this manner, future attempts become more certain and easy.

However, the success of the subsequent trials to introduce a bougie, does not always depend on the instrument having been once or twice passed. Sometimes it can be introduced to-day, but not to-morrow; and in this state the case may continue for weeks, notwithstanding every trial which can be made. But, according to Mr. Hunter, the introduction of the bougie generally becomes gradually less difficult.

According to Delpech, when the stricture is not very close, and permits the urine to flow out in a moderate jet, a fine gum elastic bougie steadily pushed on, while the urethra is rendered tense by the penis being drawn forwards, will pass as far as the bladder after some little difficulty, at the contracted point of the canal. If there exist at the same time a slight swelling of the sides of the passage, the instrument may not have consistence enough to overcome the obstacle, which may be in other respects only moderate. In this circumstance, Delpech recommends the use of a hollow but fine bougie, containing a whalebone stilet, whereby the necessary suppleness and consistence of the instrument will be united. But, he observes, the swelling of the parietes of the canal is not always uniform;

quence, deviations in the course of the passage. Also, he says, though ulcerations in it are very uncommon, yet they do occur; and their cicatrices are sometimes accompanied with deformity: hence, unusual peculiarities in the shape of the canal in the situation of the stricture. Possibly, by various examinations made with a bougie, the principal difficulty to its introduction may be found to lie especially on one particular side of the passage, so that a determinate inclination of the end of the bougie would elude the impediment. In such a case, Delpech has found great advantage in the use of fine flexible catheters, or hollow bougies, containing a small leaden stilet; the end of an instrument of this kind being capable of receiving and retaining a slight bend purposely given to it, and by means of which the obstacle at the contracted point of the canal is avoided, and the catheter or bougie passes into the bladder. Delpech then adverts to other examples, in which the stricture is such that no bougie can penetrate it. If the stricture and attendant swelling be then of small extent, he first employs catgut bougies of greater or less fineness, softening their ends by biting them, and letting the saliva penetrate them, so as to give them the form of a small, very supple pencil. When the catgut (as often happens in such a case) passes beyond the obstruction, Delpech fastens it to the penis, keeps the patient perfectly quiet, and changes the dilating substance every two hours, increasing its diameter every time. Immediately there is room enough for the admission of a small bougie (which should be before the end of the day), he employs the latter, and relinquishes the catgut. A catgut bougie, he says, ought to be changed thus frequently, because the moisture of the passage makes it swell, and untwists it in an irregular manner, so that knots are liable to be formed and render its extraction very difficult and painful, attended sometimes with an actual laceration. The catgut may even break, when it has been left in the passage too long and the surgeon attempts to withdraw it. What remains behind may then glide into the bladder, and become the nucleus of a calculus.—(*Delpech, Clinique de Chir. p.* 273.)

When the passage is very small, it is not easy to know whether the bougie has entered the stricture or not; for bougies as slender as those which must be at first employed, bend so readily, that the surgeon is apt to fancy that they are passing along the urethra, while they are only bending. Mr. Hunter advises the surgeon first to make himself acquainted with the situation of the stricture, by means of a common-sized bougie; and then to take a smaller one, and when its point arrives at the stricture, the instrument is to be gently pushed forwards, but only for a short time. If the bougie has passed farther into the penis, the surgeon may know how far it has entered the stricture, by taking the pressure off the bougie; for *if it recoil*, he may be sure that *it has not passed*; at least, has not passed far, but only bent. On the contrary, *if it remain fixed and do not recoil, it has certainly entered the stricture.*

However, the preceding remarks are said not to be so applicable when a very fine bougie is employed, which may become bent without our being aware of the circumstance.

For very close strictures, catgut bougies, or the smallest elastic gum catheters, are sometimes the most successful instruments to begin with; the latter I can recommend from repeated experience.

A bougie may frequently be introduced a little way, for instance, only one-tenth of an inch, and then it bends, and cannot be pushed farther. To determine whether this is the case, Mr. Hunter says it is necessary to withdraw the bougie and examine its end. If the end be blunted, we may be sure that the bougie has not entered at all: but if it be flattened for an eighth or tenth of an inch, be grooved, or have its outer waxen coat pushed up to that extent, or if there be a circular impression made upon the bougie, or only a dent on one side made by the stricture, we may be sure that the instrument has passed as far as these appearances extend. It then becomes necessary to introduce another of exactly the same size, and in the same manner, and to let it remain as long as the patient can bear it or convenience will allow. By repetitions of this plan the stricture will be overcome.

When wax bougies are employed, Sir A. Cooper in his lectures recommends the surgeon always to give them the natural curvature of the passage before their introduction. He also approves of the plan of warming the bougie first used, so that it may be soft enough to receive the impression of the stricture, and show its form and situation. After the first bougie is withdrawn, he directs one of rather larger size to be introduced, and as soon as this is taken out, another of still larger size to be introduced. On repeating the operation, two bougies are again introduced; the first being of the same size as that last used, and the second of an increased diameter. By continuing this method, he assures us that strictures may be more speedily cured than in the ordinary mode. He does not consider it necessary to let the bougie remain any length of time in the urethra.

Mr. Hunter remarks, that the time which each bougie ought to remain in the passage must be determined by the feelings of the patient; for, if possible, no pain should ever be given. If the patient should experience very acute pain when the bougie is passing, it ought not to be left in the urethra above five, or at most ten minutes, or not so long if the pain be exceedingly severe. Each time of application should afterward be lengthened so gradually as to be imperceptible to the feelings of the patient and the irritability of the parts. Mr. Hunter affirms that he has known many patients who could not bear a bougie to remain in the passage ten, or even five minutes, till after several days, and even weeks, but who in time were able to wear the instrument for hours, and this at last without any difficulty. The best time for keeping a bougie in the urethra is when the patient has least to do; or in the morning while he is in bed, if he can introduce the instrument himself.

The bougie should be increased in size according to the facility with which the stricture becomes dilated, and the ease with which the patient bears the dilatation. If the parts are very firm or irritable, the increase of the size of the bougie should be slow, so as to allow them to become gradually adapted to the augmented size of the instrument. But if the sensibility of the parts will allow, the increase of the size of the bougie may be somewhat quicker, but never more sudden than the patient can easily bear. The surgeon must continue to increase the size of the bougie till one of large size can freely pass; nor should the use of this be discontinued till after three weeks or a month, in order that the dilated part may have time to become habituated to its new position, and lose its disposition to contract again. However, Mr. Hunter believed that the permanency of a cure, effected on the principle of dilatation, could seldom be depended upon. I am decidedly of opinion with Sir A. Cooper, that no bougies should ever be used which are larger than those now usually numbered 14.

With respect to dilators, as they are called, I shall here merely observe that their use is far from being much approved by the best modern surgeons, and their employment is impossible, except when the stricture will permit the entrance of a bougie, or other instrument of small size; in which event the dilator is deemed unnecessary, because the other instrument will operate with greater facility and certainty.—(See *Macilwain on Strictures.*)

At the present day, many surgeons prefer bougies composed of metal, flexible enough to allow their curvature to be adapted to the bend of the urethra, yet sufficiently firm to retain the figure given them while they are employed. These instruments do not seem to me eligible in the commencement of the treatment, unless made with a conical point. Others use iron sounds, which, in cases where it is necessary to have an instrument possessing more firmness than a wax bougie, and having a point more unchangeably turned upwards than that of the latter instrument, may have advantages. Sir A. Cooper commonly uses what he calls a silver bougie, shaped like a catheter, but conical towards the point, and gradually increasing in breadth for some distance from it. The situation, form, and size of the stricture having been first ascertained with a wax bougie, the silver one is introduced, the point of which is passed into the stricture, and dilates it more and more the farther it enters. When this instrument is not at hand, a silver catheter may be used instead of it. Respecting the shape of catheters and instruments in general for the urethra, an observation has been

made by Mr. Stanley, which merits great attention; viz. that according to the natural course of the urethra, as indicated by careful dissection, the part of them corresponding to the curve of the urethra under the arch of the pubes should form a considerable segment of a circle, about one and a half or two inches in diameter, and the remainder be perfectly straight.—(See *Macilwain on Strictures.*) For all ordinary cases, I consider a common wax, or flexible metallic bougie, the safest and best instrument; one with which the surgeon is less apt to exert unwarrantable force, so as to occasion a dangerous degree of irritation, or, what is worse, a false passage; but, in obstinate or urgent cases, other means are certainly proper, and, among them, the conical silver bougie or sound.

CURE OF STRICTURES BY ULCERATION.

This is also accomplished by means of a bougie, or metallic instrument, and the plan may be tried both when they can or cannot be introduced through the stricture. In the first instance, the method is less proper, because the stricture admits of being dilated.

In order to cure a stricture by making it ulcerate, the bougie is to be introduced as far through the contracted part as possible, and the size of the instrument is to be augmented as fast as the sensations of the patient can well bear. In this manner ulceration will be produced in the part which is pressed; and Mr. Hunter remarks, that the cure will be more lasting, because more of the stricture is destroyed than when the parts are simply dilated. This eminent surgeon notices, however, that few patients will submit to this practice, and that few, indeed, would be able to bear it, since it is apt to bring on violent spasms in the part, attended with a very troublesome retention of urine.

If the smallest bougie cannot be made to pass a stricture, by using some degree of force, dilatation becomes impracticable; and as the stricture must be destroyed, something else must be tried. In many cases, says Mr. Hunter, it may be proper to get rid of the stricture by making it ulcerate. Bougies, intended to excite ulceration, need not be so small as in the foregoing cases, as they are not designed to be passed through the stricture; and in consequence of being of middling size, they may be more surely applied to the parts causing the obstruction. The force applied to a bougie, in this case, should not be great; for a stricture is the hardest part of the urethra; and if a bougie is forcibly pushed on, its end may slip off the stricture before ulceration has commenced, and make a false passage for itself in the corpus spongiosum urethræ.

In trying to cure strictures by ulceration, the utmost attention must be paid; and if the patient does not make water better, notwithstanding the bougie passes farther, the surgeon may be sure that he is forcing a false passage.

When the stricture has so far yielded as to allow a small bougie to be introduced, the treatment is then to be conducted on the principle of dilatation.

The attempt to remove strictures by exciting ulceration of them is at the present day almost abandoned, or only used when the stricture absolutely will not admit of other methods. The chief reasons against the practice are, the risk of forming a false passage, and its extreme tediousness.

Mr. Hunter observes, that whenever a bougie of a tolerable size passes with ease, and the parts and the patient have become accustomed to it, the surgeon need no longer attend for the purpose of introducing it. The patient may now be allowed to introduce bougies himself; and when he can do this with ease, the business may be trusted to him, as he can make use of the instruments at the most convenient times, so that they may be more frequently and longer applied. In the mean while, the surgeon should only pay occasional visits. Mr. Hunter adds, that this practice of the patient, under the surgeon's eye, by which means the former learns the art of introducing bougies, is the more necessary, since strictures are diseases which commonly recur; and, therefore, no man who has ever had a stricture, and is cured of it, should rely on the cure as lasting; but should always be prepared for a return, and keep some bougies in his possession. He should not go a journey, even of a week, without them; and the number should be according to the time which he is absent, and the place to which he is going; for, in many parts of the world, he cannot be supplied with them.

To prevent the inconvenience of a bougie slipping out, or the mischief of its gliding into the urethra, a soft cotton thread must be tied round that end of the bougie which is out of the urethra, and then round the root of the glans. This last part of the thread should be very loose. The redundant part of the bougie remaining out of the urethra surgeons usually clip off.

In many examples, in which a stricture is accompanied with excessive irritability in the urethra, much pain, and a tendency to frequent retentions of urine, when a common bougie is employed, it becomes advisable to alter the plan of treatment, and use either flexible metallic or elastic gum catheters: but to elastic gum bougies, which always tend to a straight form, and therefore do not adapt themselves to the natural course of the urethra, I have a strong objection founded on experience. Desault commonly cured all strictures by the skilful employment of flexible gum catheters, which his patients were directed to wear a certain length of time every day. These last instruments produce less pain and irritation than any kind of bougie, more especially when the wires are withdrawn: and were I to be myself afflicted with strictures, I should feel strongly disposed to attempt their removal by the use of elastic gum catheters, which are unquestionably the mildest and least painful means of cure. I have seen cases, however, in which the flexible metallic bougie seemed to cause much less irritation than any other kind of bougie; but, in general, those made of elastic gum give the least pain. Metallic instruments possess the advantage of retaining the exact curvature of the passage better than others; and, as I have observed, they enable the surgeon to employ more force, and this with more precision than can be done with a wax bougie. In ordinary cases, I believe the best plan is to begin with wax bougies, or elastic gum catheters, which may be employed of very small size, and are therefore more likely to pass the stricture. But as soon as this has been somewhat dilated, and it will admit an instrument of increased diameter, the surgeon may commence the use of metallic bougies or sounds, which are to be gradually augmented in size in proportion as the stricture yields.

CURE OF STRICTURES WITH THE ARGENTUM NITRATUM.

Wiseman mentions the plan of curing strictures or caruncles, as they were once called, by means of caustic. Fr. Roncalli also described a method of applying the lapis infernalis to strictures, in a work published early in the last century; and this is the more worthy of being mentioned, because the instrument used by him for the purpose is very much like what was subsequently proposed by Mr. Hunter.—(*Exercitatio agens novum Methodum extirpandi Caruncular et curandi Fistulas Urethræ; Brixiæ*, 1720.)

About the year 1752, Mr. Hunter attended a chimney sweeper who had a stricture. Not finding that any benefit was derived from the use of common bougies, for a space of six months, he conceived, that the stricture might be destroyed with escharotics, and the first attempt which he made was with red precipitate. He put some salve on the end of a bougie, and then dipped it in the powder. The bougie, in this state, was passed down to the stricture; but it brought on considerable inflammation all along the passage. He then introduced a silver cannula down to the stricture, and again passed the bougie with precipitate through the tube. As the patient, however, did not make water any better, and the smallest bougie could not be introduced through the stricture, it was suspected that the precipitate had not sufficient power to destroy the obstruction. Mr. Hunter was induced, therefore, to fasten a small piece of the argentum nitratum on the end of a piece of wire, with sealing-wax, and introduce the caustic through the cannula to the stricture. After having made the application three times, at intervals of two days, he found that the man voided his urine much more freely, and on applying the caustic a fourth time, the cannula went through the stricture. A bougie was introduced for a little while afterward, and the man completely recovered.

Having experienced this success, Mr. Hunter tried to invent an instrument better suited to the purpose than the above contrivance; and one was devised, although

ne acknowledges that it was not perfectly adapted to strictures in every situation in the urethra. He remarks, that the caustic should be prevented from hurting the unaffected part of the urethra, by introducing the active substance through a cannula down to the stricture; and that it should be capable of protruding a little beyond the end of the cannula, by which means it will only act upon the stricture. The caustic should be fixed in a small portcrayon, and it is necessary to have a piece of silver of the length of the cannula, with a ring at one end and a button at the other, of the same diameter as the cannula. The button forms a kind of plug, which should project beyond the end of the cannula in the urethra, so as to make a rounder end; or, as Mr. Hunter says, the portcrayon may be formed with this button at its other end. The cannula, with the button, is to be passed into the urethra, and when it reaches the stricture, the silver plug should be withdrawn, and the portcrayon with the caustic introduced in its place; or if the plug and portcrayon are on the same instrument, then it is only necessary to withdraw the plug and introduce the portcrayon with the caustic. The plug, besides giving a smooth rounded end to the cannula, answers another good purpose, by preventing the tube from being filled with the mucus of the urethra when the instrument is passing inwards, which mucus would be collected in the end of the cannula, dissolve the caustic too soon, and hinder its application to the stricture.

When the stricture was beyond the straight part of the urethra, Mr. Hunter owned that it was difficult to apply caustic to the disease through a cannula.

A better mode of applying lunar caustic to strictures was afterward suggested by Hunter, and introduced into practice by Sir E. Home. This gentleman directs us to take a bougie of the size that can be readily passed down to the stricture, and to insert a small piece of lunar caustic into the end of it, letting the caustic be even with the surface, but surrounded every where laterally by the substance of the bougie. This should be done some little time before it is required to be used; for the materials of which the bougie is composed become warm and soft by being handled in inserting the caustic; and, therefore, the hold which the bougie has of the caustic is rendered more secure after the wax has been allowed to cool and harden. The bougie thus prepared is to be oiled and made ready for use; but before passing it, a common bougie of the same size is to be introduced down to the stricture in order to clear the canal, and to measure the exact distance of the stricture from the orifice of the urethra. This distance being marked upon the armed bougie, it is to be passed down to the stricture as soon as the other is withdrawn. The caustic, in its passage, is scarcely allowed to come into contact with any part of the membrane, because the point of the bougie, of which the argentum nitratum forms the central part, always moves in the middle line of the canal; and, indeed, the quickness with which it is conveyed to the stricture, prevents any injury of the membrane lining the passage when the caustic accidentally touches it.

In this mode, the caustic is passed down with little or no irritation to the lining of the urethra; it is applied in the most advantageous manner to the stricture, and can be retained in that situation sufficiently long to produce the desired effect.

The reasons urged in favour of the employment of bougies armed with the lunar caustic are, that a permanent cure is effected, which common bougies cannot accomplish; that the pain arising from the application of the argentum nitratum to the stricture is very inconsiderable; and that neither irritation nor inflammation is found to ensue. The meaning of these remarks, however, is to be received as a general one, liable to exceptions. Indeed, Sir E. Home himself acknowledges that some inconveniences occasionally follow the use of armed bougies. He remarks, however, that "whatever, *a priori*, might be supposed to be the effects of so violent an application to a membrane so sensible and irritable as the urethra, and I will admit that it is very natural to conceive they would be very severe, the result of experience, the only thing to be relied on, evinces the contrary. The pain that is brought on is by no means violent; and neither irritation nor inflammation is found to take place.

That cases do occur in which strictures have produced so much mischief, and rendered so great an extent of the canal diseased, that the use of the caustic has proved unsuccessful, is certainly true; and several of these cases have fallen within my own knowledge. But when it is stated that none, even of these, were made worse by its use; that no bad consequences attend it; and that no other mode, at present known, is equally efficacious; any occasional want of success cannot be considered as an objection to this mode of practice.

But if the apprehension of violent effects from the caustic, however ill-founded, cannot be removed, let the alternative be considered; namely, the only operation previously in use, where a stricture cannot be dilated by the bougie.

In those cases, we are obliged to have recourse to means certainly more severe and violent, laying open with a knife the diseased urethra, and passing through the divided parts a flexible gum catheter into the bladder. This I have done myself, and have frequently seen performed by Mr. Hunter, and it always succeeded; neither bringing on so much inflammation as was expected, nor being attended with any symptoms of irritation.

This practice has by other surgeons been carried still farther; the portion of diseased urethra has been dissected out and entirely removed; nor has so severe an operation always brought on untoward symptoms; and patients have recovered.

If the membrane of the urethra, when diseased, is capable of suffering so much injury without any consequent symptoms of irritation, it cannot be doubted, that it will bear with impunity to be touched in a very partial manner, several different times, with lunar caustic."

Sir Everard afterward proceeds: "Having met with a number of facts from which a general principle appears to be established, that the irritable state of a stricture is kept up, and even increased, by the use of the bougie, but lessened and entirely destroyed by the application of lunar caustic, I am desirous to communicate my observations upon these facts, and to recommend the use of the caustic in many cases of irritable stricture, *in preference to the bougie.*

As the use of the caustic upon this principle is, I believe, entirely new, and is contrary to every notion that has been formed upon the subject, it will require something more than general assertion to gain even the attention of many of my readers, still more their belief: I shall therefore detail the circumstances as they occurred, by which I conceive the propriety of this practice to be established; and afterward make some observations upon the principle on which it depends.

My connexion in practice with Mr. Hunter afforded me opportunities of attending to cases of stricture in all their different stages; many of them brought on during a long residence in India, attended with great irritability, and exceedingly difficult of cure.

One case of this kind admitted the passing of a small bougie; but, in the course of three years, very little was gained by a steady perseverance in the use of that instrument, either in dilating the canal or palliating the symptoms of stricture: this made me look upon the bougie as less efficacious than I had always been taught to believe it. I was willing, however, to consider this as an uncommon case, depending more on the peculiarities of the patient's constitution than on the nature of the disease; but I found, on a particular inquiry, that several other gentlemen from India were under circumstances nearly similar; the bougie only preventing the increase of the stricture, but being unable to dilate it beyond a certain size; and when it was left off, the stricture in less than two months returned to its former state of contraction.

In August, 1794, a gentleman consulted me for some symptoms which had been considered as indicating the presence of gonorrhœa; but as they did not yield to the common treatment in the usual time, he was induced to take my advice respecting the nature of his complaint. In the necessary inquiry to obtain a perfect history of the case, among other things it was stated, that nineteen years before, there was a stricture which became very troublesome, and that Mr. Hunter, by the desire of the patient, had applied the caustic, by which the stricture was removed, and it never afterward returned. He said that he was one of the first

persons on whom the caustic had been used. From this account I was naturally led to believe that the stricture had gradually returned, and was now increased so much as to produce the present symptoms; a discharge being almost always a symptom of stricture, when it is much contracted; but, upon examining the canal, a bougie of full size passed into the bladder without the smallest impediment. I therefore took up the case as an inflammation in the urethra; and large doses of the balsam of copaiba, given internally, effected a cure.

The circumstance of a stricture having been removed nineteen years before and not returning, made a strong impression on my mind; and made me desirous to ascertain whether this practice could be employed in cases of stricture in general, and the cure produced by it equally permanent. A short time afterward, I had an opportunity of trying it in the following case.

A captain in the East India Company's service, in September, 1794, applied to me for assistance. His complaints were great irritation in the urethra and bladder, constant desire to make water, and an inability to void it, except in very small quantities. These symptoms had been at first supposed to arise from gonorrhœa, afterward rendered more severe by catching cold; but, not yielding to the usual remedies for gonorrhœa, they were investigated more minutely, and a stricture was discovered in the urethra. The mode of treatment was now changed, and the bougie employed; but its use aggravated all the symptoms, and brought on so great a degree of irritability in the bladder and urethra, that there was an alarm for the patient's life, which was the reason for applying for my assistance.

Besides the local symptoms, this patient had those of quick pulse, white tongue, hot and dry skin, loss of appetite, and total want of sleep, with frequent attacks of spasm in the bladder and urethra. A very small flexible gum catheter was passed, and the water drawn off, in quantity about a pint, which gave him great relief: this was repeated morning and evening, to keep the bladder in as easy a state as possible; but in other respects he continued much the same.

As the present symptoms were brought on by the use of the bougie, little good was to be expected from that instrument; and where the urethra had been so easily irritated, and was disposed to continue in that state, there was no prospect of the use of the bougie afterward effecting a cure. These circumstances I explained to the patient; and mentioned, in proof of my opinion, the case in which so little had been effected in three years.

I then proposed to him a trial of the caustic, with a view to deaden the edge of the stricture, as the only probable means of effecting a cure. The degree of irritation was already great: I was, however, led to believe that the application of the caustic was not likely to increase it; since, by destroying the irritable part, it might lessen, and even remove, the spasmodic affection; but if, contrary to my expectation, the irritation continued, we still should be able to draw off the water, as the slough formed by the caustic would prevent the edge of the stricture from acting and obstructing the instrument.

The application of the caustic was, upon these grounds, determined on; and it was applied in the following manner.

I passed a common bougie, nearly the size of the canal, down to the stricture, to ascertain its exact situation, and to make the canal of the urethra as open as possible. The distance was then marked upon a bougie armed with caustic, of the same size, which was conveyed down as quickly as the nature of the operation would admit. It was retained upon the stricture with a slight degree of pressure: at first there was no pain from the caustic, but a soreness from pressure; in less than a minute a change was felt in the sensation of the part; it was at first a heat, succeeded by the burning pain peculiar to caustic: as soon as this was distinctly felt, the bougie and caustic were withdrawn, having remained in the urethra about a minute altogether. The soreness, he said, was entirely local, by no means severe, was unaccompanied by irritation along the canal, and he thought the uneasiness in the bladder diminished by it. He described the pain as resembling very exactly the first symptoms of gonorrhœa. This sensation lasted half an hour after withdrawing the bougie.

The caustic was applied about one o'clock in the forenoon, and he passed the day more free from irritation than he had been since the beginning of the attack, which had lasted six days. In the evening, the water was drawn off with more ease than the night before. He passed a tolerable night, and the next day continued free from irritation. On the third day, the caustic was again applied in the forenoon: the painful sensation was less than on the former application, lasted a shorter time, and in an hour after the armed bougie was withdrawn, he made water freely for the first time since the commencement of his indisposition. He said the irritation in the bladder was removed, and he felt very well; his appetite returned, he slept very well, and continued to void his urine with ease.

In this state, nothing was done till the fifth day, leaving always a day between the applications of the caustic.

On this day a common-sized bougie went readily into the bladder; it was immediately withdrawn, and the cure was considered as complete; no bougie was afterward passed, lest it might bring back an irritation upon the passage. I met this gentleman twelve months afterward, and he assured me he had continued perfectly well: and I have since learned that, in three years, there has been no return.

From the result of this case, I was encouraged to hope that the caustic might be applied to strictures in the urethra with more confidence than I had hitherto believed, since it evidently did not bring on or increase the general irritation, but, on the contrary, seemed to allay it."

The foregoing case, together with another which Sir E. Home has related, convinced this gentleman that he had discovered an effectual mode of treating such strictures as do not admit of being relieved by the common bougie. Hence, he adopted the use of armed bougies as a general practice; but he has not concealed the circumstances under which the method does not prove successful. Sir Everard informs us, that "in some constitutions, where the patients have resided long in warm climates, every time the caustic is applied to a stricture, a regular paroxysm of fever, called by the patient an ague, takes place; and this has been so violent as to render it impossible to pursue this mode of practice. Of this I have met with two instances. I consider this disposition to fever as the effect of climate, and not of any natural peculiarity of constitution; for the brother of one of these patients laboured under the same disease, but as he had not been in warm climates it was removed by the caustic, without his experiencing such attacks."

In *gouty* constitutions, attacks of the gout have in two instances brought on spasmodic constrictions, after the stricture had been removed by caustic. This, however, cannot be called a failure of the caustic. It only shows that gout can effect strictures and reproduce them.

In some patients the strictures are so obdurate, that the use of the caustic is necessary to be continued for a longer time than the parts can bear its application, or even that of the bougie passing along the urethra; irritation therefore comes on and stops the progress of the cure, and when the same means are resorted to again, the same thing takes place. The cases of failure of this kind that I have met with, some of which may yet ultimately be cured if the patients will take the necessary steps for that purpose, amount in all to six.

In some patients, the stricture is readily removed by the caustic, but in a few weeks contracts again. The stricture being wholly spasmodic, the caustic, by taking off the spasm, is allowed to pass through, and cannot completely destroy the stricture. Of this kind I have met with one instance, which I must consider as a failure, as I have hitherto been unable to get the better of it.

In those cases, where the caustic gradually removes the stricture, and brings the urethra to a size that allows the patient to make water perfectly well, if there is any return, it is not to be attributed to the failure of the caustic, but to the want of proper management, either from the caustic being too small or its use left off too soon; but all such cases are, I believe, within the power of being cured by the caustic, if its use is recurred to when that is found necessary."

The power of caustic, however, to effect a more lasting cure than other methods, begins now to be very generally disbelieved. I have known myself several patients whose disease returned after they had been apparently cured with armed bougies. Indeed, the necessity of occasionally passing a common bougie is as great after this treatment as after others; an important fact, which Baron Boyer insists upon, on account of the many relapses with which he is acquainted.—(*Mal. Chir. t.* 9, *p.* 227.) Delpech also assures us, that he has had abundant opportunity of learning the incurable nature of strictures; they only admit, he says, of temporary relief, and have an invincible tendency gradually to return. He declares that this is constantly the case, whatever treatment may have been adopted. It would be abusing the credulity of patients and medical men, and insulting truth to pretend the contrary. —(See *Chirurgie Clinique*, *t.* 1, *p.* 273.)

For the generality of strictures in the urethra, which do not occupy more extent of the canal than if caused by a piece of packthread being tied round it, bougies armed with lunar caustic answer very well; and so I believe do common bougies, to which the preference, as I believe, ought to be given. For cases, also, in which the urethra is diminished in diameter, for an inch or more, common bougies must be most advantageous; that is to say, when they can be introduced through the stricture, so as to cure it on the principle of dilatation.

Whether in certain cases, where no progress can be made with common bougies, it is better to try caustic, or attempt to force the obstruction with a sound, is a question on which there is a great deal of difference of opinion. "The practice of pressing firm bougies, or metallic instruments, so as to force the stricture, or to produce an ulceration of it (says a modern writer), so frequently has been found to form false passages, fistulæ, and gangrene, that I need here make no farther observation on the practice or its consequences. All the advantages that can be gained by pressure, tearing through the stricture, or producing ulceration of it, may be obtained by a careful and judicious use of the caustic, which will be found on the whole a safer application, and will be attended with less inflammation and pain."—(*Wilson on the Male Urinary and Genital Organs*, *p.* 383.) This gentleman is not, however, an advocate for the caustic in every case. "I consider it," says he, "the safest practice in cases which will not yield to the introduction of bougies, and which require a portion of the stricture to be destroyed; but the symptoms which sometimes attend its use, and the injury which may be done by its improper application, should confine it to *those* cases."—(*P.* 385.)

Sir A. Cooper, in his lectures, states his opinion, that caustic bougies ought never to be employed, except where the stricture is accompanied with fistula in perinæo, and the fistula is behind the stricture; in which case there can be no risk of a retention of urine being produced by the caustic. In France, caustic bougies have never had many advocates; under particular circumstances, however, their employment is sanctioned by Delpech. He says that the swelling of the parietes of the urethra, in the situation of the stricture, may bring them into so close contact, that no bougies nor catgut will pass, and the difficulty may be still farther increased by some slight deformity of the same point of the passage. Such, he remarks, are the cases in which he has found bougies armed with nitrate of silver of great service. His plan, however, is only to remove with caustic the impediment to the passage of a small bougie; and as soon as this can be introduced, he discontinues the caustic, and practises simple dilatation.—(*Chir. Clinique*, *t.* 1, *p.* 275.)

The following are some of the general directions given by Sir E. Home, how to apply lunar caustic to strictures.

"The distance of the stricture from the external orifice is to be measured, and the canal cleared by passing a common bougie fully as large as that which is armed. The armed bougie, with the distance marked upon it, is then to be introduced and applied to the stricture: when it is brought in contact with the obstruction, it is to be steadily retained there, with a moderate degree of pressure at first, and less as it is longer continued, since the bougie becomes soft by remaining in the urethra, and readily bends if the pressure is too great. The time it is to remain depends a great deal upon the sensations of the patient, and the length of time the parts have been diseased; but on the first trial it should be less than a minute, as it then commonly gives greater pain than on any subsequent application. The pain produced by the caustic is not felt so immediately as it would be natural to expect; the first sensation arises from the pressure of the bougie on the stricture; a little afterward, there is the feeling of heat in the parts; and lastly, that of pain.

As soon as the caustic begins to act, the surgeon who makes the application is made sensible of it by the smaller arteries of the parts beating with unusual violence, which is very distinctly felt by the finger and thumb that grasp the penis.

The pain that is brought on by the caustic lasts for some time after it is withdrawn; but this period differs in almost every patient, being sometimes extended to half an hour, and sometimes only a few minutes.

The kind of pain is heat and soreness, which is not severe, not being accompanied with the peculiar irritation upon so many occasions experienced by patients who have strictures; an irritation that cannot be described, which is most insupportable, and is too often brought on by dilating strictures with the bougie." In the vol. from which the above directions are taken, Sir E. Home recommends the patient to make water as soon as the armed bougie is withdrawn; but in a subsequent vol. he explains his change of opinion upon this point: "I not only have no wish that the patient should make water immediately after the application but would rather that it be retained some time."—(*On Strictures*, *vol.* 3, *p.* 51, 8*vo. Lond.* 1821.)

"It happens not unfrequently," he says, "that at the first time of making water, some blood passes along with it. This is rather favourable; as, when the parts bleed, the stricture usually proves to be so far destroyed, that at the next trial the bougie passes through it. Every other day appears in general to be as often as it is prudent to apply the caustic. I have, however, done it every day in very obstinate cases where the parts are less sensible, without any detriment."

In his third volume, he states that he now rarely passes the bougie oftener than every third day, and never when the pain from the last application has not entirely gone off. He also never continues any one application beyond the time when the pain begins to extend farther than the spot to which the armed bougie is applied.—(*Vol.* 3, *p.* 51.)

The bougie which is passed down to prepare the way for the caustic and measure the distance of the armed bougie, must be made of soft materials, that it may readily receive an impression from the part against which it is pressed; and its colour should be light, so as to admit of those impressions being more distinctly seen. With the assistance of such bougies, the surgeon can discover the size and shape of the orifice of the stricture, ascertain with accuracy the progress of the caustic upon it, see whether it is on one side of the canal or equally all round, and apply the caustic accordingly.

"When the soft bougie passes through the stricture, by leaving it in the canal a few minutes, it can be known whether the stricture is completely destroyed or only relaxed; in the last case, there is an impression on the side of the bougie."—(*Home on Strictures*, *vol.* 1.)

I think the advice given by Delpech, not to let the end of the caustic be covered with any greasy substance, is good; for certainly its action would thus be lessened, or even defeated. At first he applies the caustic half a minute, and afterward a minute, if the patient's feelings will permit. The application is repeated every two or three days, and before each time the passage is examined with a small bougie, which, if it can be insinuated through the stricture, is used instead of that armed with lunar caustic.—(*Chir. Clinique*, *p.* 276.) Delpech regards caustic as an application liable to be attended with serious consequences and unfit for practice, in cases where either several points of the canal would need its repeated use, or where the stricture is accompanied with an extensive firm thickening of parts, including the parietes of the canal and all the perinæum. In the first case, on discovering a second stricture, he has recourse without delay to the plan of forcing the obstruction with a conical sound if a catgut bougie cannot be passed. Many of Sir E. Home's cases, however, were of this description, and yet successfully treated with caustic.

From time to time proposals have been made to perforate very bad, extensive, and unyielding strictures with a pointed or cutting instrument, applied through a tube. In cases of permanent stricture, where the part is irregularly thickened, and so indurated as to resemble cartilage, and the canal so contracted that it is either quite impermeable, or will only admit a bougie of the smallest size, Mr. Stafford disapproves of attempting the cure either by exciting ulceration, or by forcing a passage through the stricture with a conical sound, or by the use of caustic, or by cutting down to the obstruction through the perinæum. Of course, when a small bougie can be introduced through the stricture, several of these plans must be quite unnecessary; because the best treatment can be successfully continued on the principle of dilatation, unless it be argued that the cartilaginous induration of the stricture will defeat the method; a point on which much doubt may be entertained. Instead of these plans, and especially in preference to the employment of armed bougies, Mr. Stafford recommends the use of what he calls the lanceted stilet, with which he divides the stricture. For this purpose, he has invented two instruments; one for the division of permanent strictures, which yet admit of a small bougie or wire being passed through them, the other for the division of those strictures which are impervious. The instrument for the latter cases he calls the double lanceted stilet; it consists of a round silver graduated sheath, open at both ends, of the size of catheter No. 10, but with rather a less curve, and furnished with a stilet which is also hollow, and open at both ends. At one end of the stilet are two oblong lancets; and at the other a handle resembling a button. When the instrument is complete, the stilet fits into the sheath; so that, by pushing the handle, the lancets will project from the extremity of the tube, and by drawing it back they will recede again. The instrument is passed over a wire down to the stricture, and the lancets are thrust forwards on each side of it, by which means the contraction is made as large as the natural size of the urethra. The armed stilet, for the division of impervious strictures, resembles that which has first been described, excepting that the stilet is solid and furnished with only one lancet. The exact distance of the stricture from the orifice of the urethra having been first ascertained, the smallest catheter capable of containing a wire is to be introduced into the bladder. The wire, which is double the length of the catheter, and blunted at one end so that it may not injure the bladder, is then pushed forwards, and the catheter gradually withdrawn. The armed catheter is then passed over the wire until its point rests against the stricture, when the handle of the stilet is to be gently and gradually pressed. As soon as any impression is made, the lancets should be allowed to retire into their sheaths, and the blunt point of the instrument be urged forwards. If it should not pass on, the lancets may be made to project again. After the stricture has been divided, the armed catheter should be withdrawn, and one of elastic gum introduced. Mr. Stafford recommends this to be kept in for a day or two, in order to prevent the union of the divided parts, and the possibility of extravasation of urine. After its removal, a bougie is to be passed twice a week, or oftener, according to circumstances. The other kind of stilet for impervious strictures is to be used in the same manner, except that it is not passed over a wire.—(See *Stafford on Strictures*, *p.* 71, *&c.*) This gentleman adduces many examples of the success of the foregoing treatment, and he states that, with moderate care and skill, there will be no risk of making a false passage. Neither do his accounts mention any troublesome degree of hemorrhage as being the result of the method. On the whole, I consider the practice may be useful in certain cases of impervious stricture; but that, in other instances, the milder plan of dilating the obstruction should be first tried.

CURE OF STRICTURES WITH THE POTASSA FUSA.

Mr. Whately argues, that strictures are not merely contracted fibres of the urethra, but really diseased portions of the membrane lining that canal, with a continued disposition to increased contraction. Hence, he conceives that a remedy, calculated both to remove the diseased affection and to dilate the contracted part, might perfectly cure the complaint, without putting the patient to the inconvenience of wearing a bougie. Such a remedy, he says, is caustic, when judiciously used; but, instead of lunar caustic, he recommends the potassa fusa, which, he says, when used in the manner, and with the precautions about to be described, will be found to possess singular efficacy. Of its safety he is also as well convinced as of its efficacy.

However, if the potassa fusa be applied while the parts are in a highly inflamed or irritable state, or (as Mr. Whately expresses himself) tending to gangrene; if the habit be bad, and the patient very far advanced in years, the most mischievous effects may be expected from the application; and the use of any kind of caustic, under such circumstances, for strictures in the urethra, is censured as dangerous in the extreme.

Mr. Whately represents, that if the patient be affected with fever, or any other acute disease; if he be much indisposed from any cause; if, in particular, he have a gonorrhœa, attended with much inflammation and irritation in the urethra; if the prepuce, glans, or any other part of the penis, or the parts adjoining to it, be swelled and inflamed; if the urethra, and especially the strictured part of it, be so irritable as not to bear the touch of a bougie; the use of the caustic is for the present forbidden. Mr. Whately also enjoins great caution in applying this remedy to persons advanced in years. Even when no objections of the above kind exist, the caustic should not be resorted to in the first instance. In every case of stricture, before venturing to employ the caustic, we ought to be able to pass into the bladder a bougie of at least a size larger than one of the finest sort. This is necessary, both to let the caustic be applied to the whole surface of the stricture, and to relieve a retention of urine, should it occur during the use of the caustic.

When a bougie of the preceding description can be introduced, without occasioning pain, faintness, or great dejection of spirits, the use of caustic may commence immediately, provided none of the above-described objections exist.

When the urethra is very irritable, Mr. Whately recommends a common bougie to be introduced every day, and kept in the urethra; at first, for a few minutes only; but, by degrees, for a longer time; till the irritability of the parts has been sufficiently lessened.

When the urethra is rendered so impervious by a stricture, that a small bougie cannot be passed into the bladder, which viscus is also in a painful inflamed state, Mr. Whately asserts, that caustic, in any form or quantity must not be immediately employed; but that the stricture should be first rendered capable of allowing a bougie a little larger than one of the finest size to be introduced into the bladder. When this is done, the urine is more freely evacuated, and the consequent irritation and inflammation of the bladder lessened, if not removed, together with the danger of a retention of urine. Caustic may then be advantageously conveyed into the centre of the stricture.

Mr. Whately considers the practice of at once thrusting down, in this sort of case, an armed bougie considerably larger than the narrowest part of the contracted canal, as most dangerous, and horridly painful. For, says this gentleman, it frequently happens, that nearly the whole of the urethra anterior to the bulb is so much contracted by numerous and uncommonly rigid strictures, that it is impossible, by any art whatever, to dilate the passage to its natural size. If, therefore, the canal, while in such a state, be rudely torn open by a large caustic bougie, hemorrhage, pain, dangerous suppressions of urine, inflammation, mortification, and death itself, must sometimes inevitably ensue,—even before the caustic can be applied to the principal seat of the disease. In cases like the one just mentioned, the first step, preparatory to the use of the caustic, should be, according to Mr. Whately, to dilate the strictured part of the urethra; for which purpose, he advises the slow and gentle introduction of a fine bougie, with its point inclined to the lower side of the canal, in order to avoid the large lacunæ, situated on its upper part. When the surgeon, by steady perseverance and dexterity, has succeeded in getting a fine bougie through the worst stricture into the bladder, the instrument should be worn, for a few hours every day till the passage is sufficiently dilated to admit a larger one.

Mr. Whately, after explaining that caustic potassa ought not to be applied to strictures of the urethra till

a bougie of a proper size can be passed into the bladder; pointing out the methods to be taken, before applying this caustic; and enumerating certain cases and circumstances in which its employment is interdicted; next proceeds to describe the mode of practice which it is the particular object of his book to recommend.

For the purpose of arming a bougie, Mr. Whately advises us to put a small quantity of caustic potassa upon a piece of strong paper, and to break the bit of caustic with a hammer into small pieces of about the size of large and small pins' heads. In doing this, care should be taken not to reduce it to powder. Thus broken, it should be kept for use in a phial, closed with a ground stopper. The bougie should have a proper degree of curvature given to it, by drawing it several times between the finger and thumb of the left hand.

Mr. Whately next acquaints us, that before the caustic is inserted into the bougie, it is necessary to ascertain the exact distance of the stricture (to which the caustic is to be applied) from the extremity of the penis. For this purpose, the bougie, which should be just large enough to enter the stricture with some degree of tightness, ought to be gently introduced into the urethra; and when its point stops at the stricture, which it almost always does before it will enter it, a notch is to be made with the finger-nail, on the upper or curved portion of the bougie, on the outside of the urethra, exactly half an inch from the extremity of the penis. When the bougie is withdrawn, a small hole, about the sixteenth part of an inch deep, should be made at the extremity of its rounded end. A large blanket-pin, two inches and a half in length, with the head struck off, will answer the purpose; the hole being made with the point of the pin. The extremity of the bougie should then be made perfectly smooth with the finger and thumb, taking care that, in doing this, the hole in its centre be not closed. Some of the broken caustic should then be put on a piece of writing paper, and a piece less in size than the smallest pin's head should be selected; the particle, indeed, says Mr. Whately, cannot be too small for the first application. Let this be inserted into the hole of the bougie with a pocket-knife, spatula, or some such instrument; and pushed into it with the blunt end of the pin, so as to make the caustic sink a very little below the margin of the hole. To prevent the potassa fusa from coming out, the hole should then be contracted a little with the finger, and the remaining vacancy in it is to be filled with hog's lard. This last substance (continues Mr. Whately) will prevent the caustic from acting on the sound part of the urethra, as the bougie passes to the stricture. When the bougie is quite prepared, let it be first oiled, and immediately afterward introduced, by a very gentle motion, with the curvature upwards, as far as the anterior part of the stricture, upon which the caustic is to be applied. In doing this, the end of the bougie, held by the finger and thumb, should be a good deal inclined towards the abdomen, on the first introduction of the instrument, in order to preserve its curvature. After it has passed about five inches, this end should be gradually brought downwards, as the bougie passes on, till it forms a right angle with the body. The bougie is known to have arrived at the stricture by the resistance made to its progress.

As soon as the bougie has reached the anterior part of the stricture, it should rest there for a few seconds, that the caustic may begin to dissolve. It should then be pushed very gently forwards about one-eighth of an inch; after which, there should be another pause for a second or two. The bougie should then be carried forwards in the same gentle manner, till it has got through the stricture. The sense of feeling will generally inform the operator when the point of the bougie has proceeded so far; but the notch in the bougie is to be an additional guide, by becoming very near the orifice of the urethra, when the end of the instrument has just got through the stricture.

The bougie should now be immediately withdrawn by a very gentle motion to the part, at which it was first made to rest awhile. Then it should be very slowly passed through the stricture a second time; but without letting the bougie stop in its passage. If the patient complain of pain, or be faint, the bougie should be immediately withdrawn; but if these effects are not produced, we may repeat the operation of passing and withdrawing the bougie through the stricture once or twice more before we finish the operation, which will take up, in the whole, about two minutes.

The first application of the potassa fusa, in this manner, gives, according to Mr. Whately's account, a very little pain. A slight scalding in making water, and a trifling discharge, during the first day or two, however, are commonly produced.

At the end of seven days, the application of the caustic is to be repeated in the same manner. When the first application has enlarged the aperture of the stricture, which may be known by passing a bougie through it of the same size as that by which the caustic was conveyed, the bougie used in the second operation should be a size larger than the one used in the first; but it must not be too large to pass through the stricture. If the patient had no pain on the first application, the bit of potassa fusa may also be trivially larger. At the end of seven days more, the armed bougie should be introduced a third time. At this and all future applications, the bougie should be increased in size in proportion as the aperture in the stricture becomes dilated. The quantity of caustic, however is never to be increased in a ratio to the size of the bougie. In no cases whatever does Mr. Whately apply more of the potassa fusa at a time, than a piece about the size of a common pin's head. Twelve bits of the largest size which this gentleman ever uses weigh one grain.

When there are several strictures, the potassa fusa should be generally applied to only one at a time.

An interval of seven days is what Mr. Whately generally allows to elapse between the applications of the caustic. The rule, however, may now and then be deviated from; but the potassa fusa ought never to be reapplied till the action of the last application has completely ceased. In a few instances the interval may only be five days; in some others it may be eight, nine, or even a longer space.

In the above method of using the potassa fusa, Mr. Whately represents, that this substance is equally diffused over every part of the strictured surface, and only *abrades* the membrane of the stricture without producing a slough. The *degree* of this abrasion, he says, may be increased or lessened, as circumstances dictate, by paying attention to the quantity of the caustic.

The foregoing account will convey an adequate idea of Mr. Whately's method, in which I never saw any recommendation but that of novelty. To *abrade* without destroying is rather too nice a distinction for a practical man, doing business, as it were, in the dark. Nor can I conceive, that a liquid caustic (for so it is represented as becoming) can be applied with the accuracy to strictures which Mr. Whately seems to suppose happens. This, however, is merely my own sentiment, and I do not wish to conceal, that there are yet a few surgeons who believe, that Mr. Whately's plan is the most eligible for all cases in which the stricture is irritable or far advanced.—(See *Howship's Pract. Obs. on the Urinary Organs*, p. 207.) On the other hand, I know some very eminent surgeons, who formerly took up this practice with great zeal, and now have entirely abandoned it. I consider it myself the worst and most random mode of applying caustic to strictures, and more likely to act on the sound than the diseased portion of the urethra. Sir A. Cooper is decidedly averse to the use of caustic alkali, which, he says, is much too soluble, and calculated to produce a great deal of inflammation by running over an extensive surface. In this advice I fully concur.

Upon the whole I may safely declare, that caustic bougies of every kind are now much less frequently used by the best surgeons in London than they were about twenty years ago. Several distinguished practitioners, who to my knowledge were then accustomed to recommend and employ them, have at present returned either to the use of common bougies, or those made of metal or elastic gum, to which, after many comparative trials, I acknowledge a general, but not a universal preference seems to me to be due. We learn from M. Roux, that caustic bougies never had many advocates in France; and the inquiries which he made when he was in London, authorized him to announce to his countrymen after his return, that such instruments were not more in general favour here than they were at Paris.—(See *Voyage fait à Londres en* 1814, *ou Parallèle de la Chirurgie Angloise, &c.* p. 315.)

Cases of stricture, where the disease is far advanced, of long standing, and attended with such obstruction that no kind of common bougie can be introduced, appear to me to be examples in which perforation on Mr. Stafford's plan may be justifiable. Instead of this, however, some surgeons would prefer the employment of a common bougie, or a conical sound made of iron, silver, or platina, with sufficient force to make its way through the stricture by laceration. If the stricture occupy a considerable length of the passage, I believe a passage through it must sometimes be attempted on the principle of exciting ulceration, and that for this purpose a sound or metallic catheter should be employed. An interesting case of cartilaginous stricture and fistulæ in perinæo is recorded by Delpech, where a false passage was made with a lunar caustic bougie, which actually pierced the rectum; two days after this accident the stricture was forced with a conical sound, which fortunately eluded the false passage and entered the bladder. An abscess in the perinæum followed, but the case ended well under the use of elastic gum catheters.—(*Chir. Clin. p.* 280.) When the treatment of strictures brings on severe shiverings, followed by febrile symptoms, opium is the best medicine to be given, and the introduction of instruments into the passage should be suspended. When hemorrhage from the urethra is occasioned by the use of bougies or other instruments, cold evaporating lotions to the perinæum, or the cold bath itself, is the most effectual way of suppressing it. In one case, mentioned by Sir A. Cooper in his lectures, he was under the necessity of dividing the artery of the bulb; a measure which completely succeeded.

[So numerous have been the failures of surgical treatment in strictures of the urethra, that many surgeons have considered a severe stricture, and especially a series of strictures in this canal, the most incurable and unmanageable of surgical diseases. The great number of strictures found in the incurable wards of our hospitals, alms-houses, and infirmaries have long rendered this affection an opprobrium chirurgiæ. The most skilful will often do mischief with the armed bougie, and, if they by caution avoid this, still their failure will often be a painful source of mortification.

Professor Jameson, of Baltimore, has introduced an operation by which he has succeeded in curing a large number of obstinate cases; and although he only advises and performs this operation in the worst instances of severe, long-continued, and complicated stricture, the proportion of cures has been greater than is ordinarily found in the practice of any surgeon who treats all kinds of cases indiscriminately by any of the former methods.

In the *Amer. Med. Recorder* for 1824, Dr. Jameson has published an essay on stricture of the urethra, in which he reports a number of cases, with their treatment and results. Several of these cases came under my own notice; and during my former residence in Baltimore, I witnessed his operation several times, and had an opportunity of seeing his success, and the entire removal of the disease.

This operation consists in opening the urethra through the perinæum, and introducing a flexible catheter through the penis into the bladder, which is suffered to remain until the wound in the urethra is united.

The patient is tied as for lithotomy, and a sound introduced as far as it can be passed, which serves as a guide, if it can be introduced as far as the bulb. An incision is now made through the perinæum, and the urethra laid open. In bad cases he advises to divide the triangular ligament both above and below the urethra. The fore-finger is then to be introduced through the remainder of the stricture. When it is necessary to divide the muscles surrounding the membranous part of the urethra, a director is first introduced, and the incision made with a scalpel or bistoury, when the finger may be passed into the bladder. A flexible catheter is now passed through the penis into the bladder, and the wound is placed in the most favourable circumstances to unite.

Though this operation is as severe, and even sometimes more difficult than lithotomy, Dr. J.'s experience has shown that it is seldom attended with danger. The only cases in which this operation would be advisable are those in which no sound or staff can be passed into the bladder, and herein consists the difficulty of the operation. It is a means, however, which has afforded relief in cases which had otherwise been abandoned as hopeless.—*Reese.*]

URETHRA, FALSE PASSAGE IN. One of the worst consequences of using catheters and bougies in an improper manner, is the rupture of the urethra, or the formation of a false passage by ulceration. With bougies this accident is generally occasioned by trials to excite ulceration by the application of the end of the bougie to the stricture, when this instrument cannot be passed through it. When once the new passage has been formed, whenever the bougie is introduced it cannot be hindered from going into the false track, and its action on the stricture is altogether frustrated.

In this kind of case, Mr. Hunter has advised the following operation to be practised. Pass a staff or any such instrument into the urethra as far as it will go, which will probably be to the bottom of the new passage, and this, we may be certain, is beyond the stricture. Feel for the end of the instrument externally, and cut upon it, making the wound about an inch long, if the disease be before the scrotum; and an inch and a half, or more, if in the perinæum. If the new passage be between the urethra and body of the penis, you will most probably get into the sound urethra before you come to the instrument or new passage. If so, introduce a probe into the urethra through the wound, and pass it towards the glans penis, or, in other words, towards the stricture. When it meets with an obstruction, this must be the stricture, which is now to be got through, and afterward dilated. To complete the operation, withdraw the probe, and, instead of it, introduce a hollow cannula forwards to the stricture. Then introduce another cannula from the glans downwards, till the two tubes are opposite each other, having the stricture between them. An assistant is now to take hold of the urethra on the outside with his finger and thumb just where the two cannulæ meet, in order to keep them in their places. Through the upper cannula next introduce a piercing instrument, which is to perforate the stricture, and enter the lower cannula. The piercing instrument is now to be withdrawn, and a bougie introduced through the first cannula and stricture into the second cannula. The tubes are to be withdrawn, and the end of the bougie in the wound directed into the bladder, through the farther portion of the urethra. It may also be necessary to lay the whole of the false passage open, in order to make it heal; for, otherwise, it might still obstruct the future passage of bougies into the proper canal.

When the new passage is between the skin and urethra, the surgeon must extend his incision more deeply, for the purpose of finding out the natural passage. Then he is to proceed as above explained.

The longer the first bougie is allowed to remain in

the canal, the more readily will the second pass. The bougies must be gradually increased in size, and used till the wound is healed. The only improvement which seems proper to be made in this plan, is to employ flexible gum catheters, which might be worn longer than common bougies, as the patient could void his urine through them.

It appears, from the observations of Mr. Stafford, that if a false passage be made, leading from one part of the urethra to another, and the urine pass through the new channel, it becomes lined by a kind of membrane, resembling that of the natural canal.—(*On Strictures*, *p.* 39, *ed.* 2.)

URINARY ABSCESSES. Extravasations of urine may be in three different states. This fluid may be collected in a particular pouch; it may be widely diffused in the cellular membrane; or, lastly, it may present itself in a purulent form, after having excited inflammation and suppuration in the parts among which it is situated. This case is termed a urinary abscess.

Such extravasations of urine always imply a rupture, either in the kidneys or ureters, the bladder or the urethra. The solution of continuity may be produced by a variety of causes. It is most frequently the effect of a forcible distention of these passages in consequence of a retention of urine. The bursting of phlegmonous abscesses into the same passages may occasion the breach. It may also be produced by the penetration of the parts with a sword or other foreign body: there are likewise examples of effusion of urine from the displacement of the cannula of the trocar after the operation of puncturing the bladder. Others are caused by false passages in the urethra, or by violent contusions of the perinæum, attended with laceration of the urethra.

In *Desault's Surgical Works* (*t.* 3) it is observed, that the ravages which extravasated urine makes are usually greater and more extensive when it enters the cellular membrane, than when it is confined in a particular cyst. The mischief is also less when the excretory passage is free, than when it is closed by any obstacle, as in cases of retention. The more or less loose texture of the parts in which such effusions happen, likewise makes a considerable difference in their progress and formation. When the pelvis or infundibulum of the kidney, or the upper part of the ureter gives way, the urine is commonly effused in the loins and the fosse iliacæ, between the peritoneum and the adjacent parts. When the lower part of the ureter or the bladder near its lower portion gives way, the extravasation is generally included within the pelvis.

But when the rupture occurs in the anterior parietes of the bladder near its upper part, and especially when it takes place at a time when this organ is extremely distended and dilated, the urine becomes effused behind and above the pubes, sometimes ascends to the epigastric region, between the peritoneum and the abdominal muscles, and, after having followed the course of the spermatic vessels, it often makes its exit at the ring, and is extravasated in the groins and scrotum. If the rupture has happened in the urethra, the most common situation of the effusion is in the perinæum and scrotum. The extravasation frequently extends to the penis and upper part of the thighs, and even sometimes propagates itself under the skin of the abdomen up to the hypochondria and sides of the chest.

There is no fluid the extravasation of which is so fatal as that of the urine. If it is not promptly discharged, it soon excites suppuration and sloughing of the cellular membrane, a gangrenous inflammation of the skin, and almost always a mortification of the parts among which it flows.

While the extravasation of urine is confined to the interior of the pelvis, and lumbar and iliac regions, without manifesting itself externally, there is no certain sign of its existence. The circumstances which may be recollected, however, joined with the symptoms which the patient complains of, may lead to a suspicion of the extravasation. Thus, when, in consequence of a retention of urine in the ureters or bladder, the patient has suddenly experienced great relief, without any of the urine having been discharged the natural way; when he has at the same instant felt a kind of pricking in the loins or pelvis; when to the ease, which lasted only a few hours, symptoms more severe than the former ones have succeeded (such as violent fever, hiccough, vomiting, &c.), an internal extravasation is to be suspected.

As soon as the extravasation is apparent externally, the case is announced by symptoms which hardly ever deceive. The preceding retention of urine; the sudden appearance of the swelling caused by this fluid; the rapid progress of the tumour; the kind of crepitation perceptible in it, like that which occurs in emphysema; the shining tension and œdema of the skin; the diminution of such symptoms as depended entirely upon the retention; are the first changes which are observable when the extravasation is somewhat considerable.

If the patient is not speedily assisted and the urine continues to be extravasated, the tumour spreads more and more; the skin assumes a red violet colour; gangrenous eschars are formed, the separation of which gives issue to a very fetid sanies, in which the smell of urine is readily distinguishable. Portions of dead cellular membrane are presently discharged together with the sanies; the ulcer grows larger; and the dressings are continually wet with the urine.

When one of the ureters has given way, and a urinary abscess is formed in the loins, the aid to be derived from surgery is limited to making an opening in the extravasation as soon as it can be felt externally. It is then not in the power of art to re-establish the natural course of the urine, or to hinder this fluid from passing through the wound and rendering it fistulous. However, there are some circumstances in which a radical cure may be attempted. For example, if the abscess were produced by a calculus lodged in the infundibulum or ureter, and it could be felt and taken hold of with a pair of forceps introduced into the opening, the extraction of the foreign body might promote the healing of the ulcer, by rendering the natural channel for the urine free.

When the opening by which the urine has become extravasated exists in the bladder or urethra, one indication that does not present itself in the foregoing case may be fulfilled, viz. the urine may be drawn off by means of a catheter passed into the bladder and kept there. By this means we not only immediately stop the progress of the extravasation, but attack the very cause of the malady, by removing the obstacles which oppose the natural course of the urine. The introduction of the catheter then becomes a matter of the most urgent necessity. This operation is often attended with the greatest difficulties. Besides the ordinary obstruction of the canal, we have also to surmount the obstacles which the urinary swellings situated in the course of the urethra create to the passage of the instrument. When these tumours are considerable, they ought to be opened before the catheter is employed. The subsidence of the swellings would render catheterism more easy. Besides, Desault was assured, by daily experience, that with a little skill, exercise, and patience, the catheter might always be got into the bladder. If, however, the thing could not be done, ought we to puncture the bladder, or have recourse to the operation of cutting into the dilated portion of the urethra between the stricture and the bladder?

Desault was an advocate for neither of these proceedings: he thought it was a more simple and beneficial practice merely to make an external opening in the collection of effused urine. This measure would both afford an outlet for the urine, and arrest the extension of the extravasation. Besides, such an opening is often indispensably requisite for the purpose of putting a stop to the symptoms depending upon the effusion and stagnation of the urine. But if the catheter can be introduced, there may be cases in which an opening would not only be useless but hurtful: for instance, when the swelling caused by the urine is of little extent, or when it is situated in the thickness of the parietes of the passage, or along its track, it almost always admits of dispersion by the simple employment of the catheter. But it seldom happens that this swelling, however small, ends in resolution; it almost always suppurates; yet, as it breaks into the urethra, the matter escapes between this canal and the catheter, and renders the making of an external opening needless. Experience teaches us, also, that when the tumour is situated in the scrotum, or between the root of the penis and the symphysis pubis, even after the healing of the incisions made in these situations, a fistula will often remain, which is very difficult of cure. With the exception of these particular cases

Desault was an advocate for opening all urinary abscesses.

In my own practice, I have never experienced much difficulty in healing fistulæ in the perinæum, after the removal of the obstruction in the urethra; and my usual plan, whether the effusion of urine be considerable or not, is always first to make a puncture or incision in the swelling, so as to obviate the risk of its increase, and then to have immediate recourse to the catheter.

The manner of opening such collections varies according as the urine may be in one cavity or widely effused in the cellular membrane. In the first case, a simple incision the whole length of the cavity will suffice for emptying and healing it. In the second, if the extravasation is extensive, the incisions must be multiplied. It would be absurd to spare the parts; for all those with which the urine has come into contact seldom escape mortification. The incisions which are made hardly ever have the effect of saving them; but by accelerating the discharge of putrid sanies and stagnant urine, they prevent mischief which would originate from a farther lodgement. At all events, when the operation is at all delayed, the destruction of all the parts in contact with this irritating fluid is inevitable. The approach of mortification is indicated by the crepitation under the bistoury, resembling the kind of noise produced by tearing parchment. The extent and depth of the incisions must be proportioned to those of the abscess. When the extravasation occupies the scrotum, long deep scarifications should be made in that part, as well as in the skin of the penis, and in every place where the urine is effused.

Practitioners unaccustomed to see such diseases would be alarmed at the extent of the sore produced by the separation of the eschars. Sometimes the whole scrotum, skin of the penis, and that of the groins, perinæum, and upper part of the thigh, mortify, and the naked testicles hang by the spermatic cords in the midst of this enormous ulcer. It is hardly conceivable how cicatrization could take place over the exposed testicles; but the resources of nature are unlimited. She unites the testicles and the cords to the subjacent parts, and drawing the skin from the circumference to the centre of the ulcer, she covers these organs again, and furnishes them with a sort of new scrotum. This statement is founded upon numerous cases in which nature always followed this course. The cicatrization of the ulcer is even more expeditious than might be apprehended, considering its extent. In all this business, what does art do? If the introduction of the catheter is excepted, which, indeed, is absolutely necessary for the radical cure, her assistance is very limited, and almost nothing, in the generality of instances; for when patients are not exhausted by the tediousness of the disorder, when they are of a good constitution and in the prime of life, they get well as quickly and certainly with the aid of a good diet and simple dressings as when they take internal medicines and use a multiplicity of compound topical applications. The practice of Desault, at the Hôtel-Dieu, consisted in applying emollient poultices until the sloughs were detached. The ulcer was then sometimes dressed with pledgets charged with styrax; but frequently mere dry lint was used, and continued till the cure was completed. If any complication occurred in the course of the treatment, suitable remedies were prescribed for it. Thus, when prostration of strength and tendency to sloughing existed, bark, cordials, and antiseptics were ordered. But, in every case, the catheter is the essential means of cure; without it the treatment is almost always imperfect, and the ulcer will not heal without leaving several urinary fistulæ.—(See *Œuvres Chir. de Desault, par Bichat*, *t.* 3, *p.* 277—287.)

URINARY CALCULI. A true explanation of the nature of urinary calculi was quite impossible, before chemistry had made considerable progress, and the methods of analysis had advanced a great way towards perfection; and, as will appear in the course of this article, all the valuable knowledge which now exists upon this subject is in reality the fruit of modern investigations. It is to be regretted, however, that our information on many points is far from being settled or complete, as any impartial and judicious reader may soon convince himself by a reference to the able and scientific views lately taken by Dr Prout, of various questions relative to the formation of gravel and calculi, and the treatment of such cases in all their varieties.—(See *An Inquiry into the Nature and Treatment of Gravel and Calculus, and other Diseases connected with a deranged Operation of the Urinary Organs*, 8*vo*. *Lond*. 1821.)

Mechanical deposites from the urine are divided by Dr. Prout into three classes. 1. Pulverulent or amorphous sediments. 2. Crystalline sediments, usually denominated gravel. 3. Solid concretions or calculi, formed by the aggregation of these sediments.

Pulverulent or *Amorphous Sediments* are described by Dr. Prout as almost always existing in a state of solution in the urine before it is discharged, and even afterward until it begins to cool, when they are deposited in the state of a fine powder, the particles of which do not appear to be crystalline. Their colour is for the most part brown or yellow, and, generally speaking, they consist of two species of neutral saline compounds; viz. the lithates of ammonia, soda, and lime, tinged more or less with the colouring principle of the urine, and with the purpurates of the same bases, and constituting what are usually denominated *pink* and *lateritious* sediments; and, secondly, the earthy phosphates, namely, the phosphate of lime, and the triple phosphate of magnesia and ammonia, constituting for the most part sediments nearly white. The two species of sediments are frequently mixed together; though the lithates generally prevail.

Crystalline Sediments, or *Gravel*, are commonly voided in the form of minute angular grains or crystals, composed, 1. Of lithic acid, nearly pure; 2. Of triple phosphate of magnesia and ammonia; and, 3. Of oxalate of lime. The crystals of lithic acid, which are by far the most frequent, are always more or less of a red colour. Those composed of the triple phosphate of magnesia and ammonia are nearly white; while others, composed of the oxalate of lime, which are extremely rare, are of a dark, blackish green colour. It is farther remarked by Dr. Prout, that these different varieties of crystalline deposites are never voided together, though they not unfrequently occur with amorphous sediments.—(*Prout*, *op. cit. p.* 79, *&c.*)

Solid Concretions, or *Urinary Calculi*, arising from the precipitation and consolidation of the urinary sediments, may be formed in any of the cavities to which the urine has access; and hence they are met with in the kidneys, ureters, bladder, and urethra. Their various appearances and chemical properties will be presently described. Most of them are believed to be originally produced in the kidneys, from which they afterward descend with the urine. To this statement, however, the cases in which calculi are formed upon foreign bodies introduced into the bladder through the urethra, an accidental wound, or some ulcerated communication between the intestines and the bladder, are manifest exceptions. In the centre of urinary calculi, bullets, splinters of bone, pieces of bougies, and wood, pins, needles, nuts, &c. are frequently observed; and it would appear that a very minute substance is capable of becoming a nucleus: a mere clot of blood, or a little bit of chaff, if not soon voided, being sufficient to lead to the formation of a stone in the bladder. The lithic acid itself is a common nucleus, even where the whole calculus is not of the same material.

That many urinary calculi are originally produced in the kidney, is certain; first, from the severe pain which the passage of such foreign bodies down the ureter always excites; and, secondly, from their being often discovered in the infundibula and pelvis of that viscus after death. This last fact is well illustrated in the first plate of Dr. Marcet's interesting "*Essay on the Chemical History and Medical Treatment of Calculous Disorders*," 8*vo*. 1817. The engraving is taken from a preparation in the Museum of Guy's Hospital. In this instance, there were several calculi closely pressed against each other; but, in another example, drawn from a specimen in Mr. Abernethy's museum, the renal concretion was composed of a single mass which represented a complete cast of the pelvis, and part of the infundibula of the kidney. In this form of the disease, the kidney loses at last all vestiges of its natural structure, and is converted into a kind of cyst filled with the extraneous substance. When so complete an alteration of the structure takes place, the secretion of urine must of course be entirely carried on by the other kidney. However, in some instances, the inconvenience thus produced is so slight, that it almost

escapes notice; and sometimes even both kidneys are diseased in a very great degree, and yet life is preserved for a considerable time.—(*Op. cit. p.* 3, 4.)

Calculi are sometimes found in the ureters, especially at the upper part; but it is not supposed, that they are originally formed there; an event not likely to happen, unless there were some cause retarding the descent of the urine through those tubes. The common belief is, that all calculi found in the ureter, are first produced in the infundibula, and pelvis of the kidney, from which they afterward descend with the urine.

The generality of calculi, however, which leave the kidney are of small size, and, consequently, after a time, and exciting some pain and inconvenience, they usually pass into the cavity of the bladder. Indeed, as Dr. Marcet remarks, the bladder is the most frequent seat of calculi: not only because all urinary concretions, or their nuclei, formed in the kidneys, tend to fall into that organ; but, also, because a stone may be, and probably often is, originally formed in the bladder itself.

Renal concretions vary considerably in their number, size, and shape. In some cases, a single small calculus has been found occupying one of the foregoing situations; while, in other instances, an innumerable collection of calculous substances are observed filling the whole of the cavity of the pelvis and infundibula of the kidney, distending its parietes, and even obstructing the passage of the urine out of this viscus, which is converted into a sort of membranous cyst. Lastly, a single stone in the kidney may acquire a very large size there; or a great number of small calculi, in the same situation, may become cemented together, so as to form one mass of enormous dimensions, and the shape of which invariably corresponds to the space in which it is, as it were, moulded. Hence, renal calculi often present a variety of odd, irregular figures, resembling those commonly observed in specimens of coral.

Great disorder of the stomach, frequent vomiting, and great irritability of the bladder are common effects of a calculus in the kidney. Sir A. Cooper met with a case in which the chief pain was at the anterior superior spinous process of the ileum.

It has been already remarked, that urinary concretions of large size very often exist in the kidney, without their presence being indicated by any external circumstances, or attended with any symptoms, sufficiently unequivocal to constitute a ground for suspecting the importance of their cause. On the other hand, it is very usual for renal calculi, of middling dimensions, to excite serious and alarming complaints. The reason of this difference becomes obvious, when it is recollected, that smallish concretions are readily carried with the urine into the ureter, and become fixed in the narrow portion of the tube. But very large calculi can be contained only in the upper part of this canal, where its parietes are more yielding, and the space in them more capacious.

Calculi of middling size, in their passage through the ureter, cause, at first, a feeling of heaviness, or an indeterminate sense of uneasiness, and an obtuse pain in the region of the corresponding kidney. These complaints occur at intervals of greater or less duration. At length, the pain grows more urgent and annoying, attended with flatulence, heart-burn, frequent vomiting, painful retraction of the testicle, and sometimes acute fever. As Sir A. Cooper has remarked, in his lectures, it is at the period, when the calculus is passing over the lumbar plexus, that a great deal of pain is felt in the groin and in the course of the anterior crural nerve, just as the spasmodic contraction of the cremaster arises at the time when the calculus is descending over the spermatic plexus. The patient makes water frequently, and in small quantities at a time; and the urine is high-coloured and bloody. The patient cannot sit upright, his body being bent forwards towards the affected side. These symptoms may have more or less duration, and then suddenly cease. They may also subside and recur several times at intervals of some days. In the latter case, the pain is felt at each attack to be situated lower in the track of the ureter. Lastly, when the symptoms have entirely disappeared, the urine is more abundant, not so high-coloured, and easily discharged, the stream sometimes bringing out with it the urinary concretion, after its entrance into the bladder.

Suppuration of the kidney, and an abcess in the lumbar region, in consequence of renal calculi, are not very common events. However, these are the only cases of the kind in which the interposition of surgery can be useful. By adverting to previous circumstances, and irregularity of the pain about the kidney, the practitioner may suspect the nature of a phlegmonous tumuor in the situation of this viscus. Whatever may be his conjectures, however, he must carefully abstain from the use of his lancet until purulent matter is plainly under the integuments. He may then safely make an opening, from which urine and pus will be discharged, and through which the calculi themselves may sometimes be felt and extracted. If they cannot be readily touched with a probe, let not the surgeon rashly conceive that he is justified in endeavouring to discover them with his knife. Their situation may be such as to baffle all his endeavours, and the operation itself might cause a most dangerous hemorrhage, and other fatal mischief. The opening of an abscess of the kidney may remain a long while fistulous, and indeed warrant the conclusion, that the healing is prevented by the presence of some extraneous substances; but a prudent practitioner will never think of performing any operation for their extraction, unless they can be distinctly felt, and nature has brought them tolerably near to the surface.—(See *Nephrotomy.*) Sir A. Cooper, in his lectures, mentions a singular case, in which Mr. Cline was able plainly to feel, in a very thin patient, a calculous situated in the kidney. He adverts also to another example, in which a great deal of purulent matter had been voided from the bowels before death, and, on opening the body, a calculus was found lodged in the ureter, between which tube and the colon an open communication existed, through which the abscess of the kidney had discharged itself into the intestines. In one particular case, related by the same experienced surgeon, a calculus, fixed in the ureter, gave rise to a renal abscess, which burst into the cavity of the abdomen, and the patient's death quickly followed.

Urinary calculi, which form upon foreign bodies accidentally introduced into the bladder, and acting as nuclei, are always single, unless the number of foreign bodies themselves happen to be greater. It is curious also to find, from the observations of Mr. Murray Forbes (*On Gravel and Gout, p.* 74, 8*vo. Lon.* 1793) and Dr. Marcet, that, in such instances, the deposition, most frequently, if not always, consists of the earthy phosphates, and especially of the fusible calculus. Thus, in the collection of Mr. R. Smith of Bristol, there is a pin, a piece of bougie, and four pieces of stick, coated with fusible matter.—(See *Med. Chir. Trans. vol.* 11 *p.* 11.) But when calculi originate from a particular diathesis, there may be many of them lodged in the bladder at the same time. Several distinct nuclei may descend successively from the kidneys, and each may increase in a separate manner. Sometimes, however calculi in the bladder, which are at first distinct and unconnected, become afterward cemented together, so as to make only one mass.

The magnitude of calculi in the bladder is generally in an inverse ratio to their number. Some hundreds have been found in one bladder; but they were not larger than a pea. One very remarkable instance has lately been recorded, in which 398 calculi, from the size of a pea to that of an olive, were found in the bladder after death. By analysis, they were found to consist of phosphate of lime, phosphate of magnesia, and uric acid.—(*Mag. der Auslandischen Literatur, Hamb. Jan. Feb.* 1822; *and Journ. of Foreign Med. No.* 35.) It is observed by Sir Astley Cooper, that when a great number of calculi are found in the bladder, the circumstance is generally attended with an enlargement of the prostate gland, directly behind which a sacculus is formed. In cases of diseased prostate gland, the bladder can seldom be completely emptied; and this partial stagnation of the urine in the sac here alluded to, is supposed to facilitate the production of calculi. From their number and collision against each other, their surfaces are generally smooth, and their shape is commonly roundish.—(See *Med. Chir. Trans. vol.* 11, *p.* 359, and *art. Prostate Gland.*) Other calculi have been met with of so large a size, that they were more than six inches in diameter. In Fourcroy's museum, and in that of the Ecole de Médecine, at Paris, may be seen some calculi which filled the whole cavity of the bladder; and in the *Phil. Trans.* for 1809, the late Sir

James Earle described an enormous stone, which he extracted after death from the bladder of the late Sir David Ogilvie, who had been unsuccessfully cut for it. This calculus, which was of the fusible kind, weighed forty-four ounces, and was of an oval shape, its long axis measuring sixteen inches, and the shorter fourteen. The average size of vesical calculi may be compared with that of a chestnut, walnut, or a small hen's egg. Their size depends very much upon their composition, the largest being of the fusible kind. Their weight differs from a few grains to upwards of fifty ounces; but on an average, it is from two to six ounces. Their weight is not always proportioned to their size; for substances of different qualities enter into their composition, and diversify their heaviness.

The urinary salts, in calculous patients, are not continually precipitated in the same quantities: in some cases, indeed, the process appears to be even suspended for a considerable time. Hence, a stone of middling size already formed, may increase but very slowly; and it has actually happened, that a calculus, which could be plainly felt with a sound, has remained more than ten years in the bladder, and yet, after all this time, been only of a moderate size.

According to Dr. Marcet, the form of urinary calculi is mostly spheroidal, sometimes egg-shaped, but often flattened on two sides like an almond.—(*P.* 50.) Sometimes the calculous matter which descends from the kidneys is in the form of minute spherical grains, which have a singular tendency to unite either to each other, or to calculi already lodged in the bladder.

When there are several loose calculi in the bladder together, they seldom lie long in contact with each other, while their size is diminutive, but are incessantly changing their situation as the patient moves about, or alters the position of his body. Hence, their increase is at first regular and uniform; but when they have attained a more considerable size, or by their numbers compose a large mass, their relative situation is more permanent, and many of their surfaces being in this manner usually covered, no longer receive any additional depositions. Every other part of these calculi, however, goes on increasing. It is thus that stones, with surfaces corresponding to those of other stones, are produced, and which are aptly denominated by the French writers "*pierres à facettes.*"

Dr. Marcet has likewise taken notice of the angular shape of certain calculi, and remarked the rare occurrence of their being sometimes almost cubic. His work contains the engraving of a species of calculus, which somewhat resembles a pear, with a circular protuberance at its broader end, apparently moulded in the neck of the bladder.

The same intelligent writer has also particularly considered the variety in the colours and surfaces of calculi, which often afford indications of their chemical nature. "When they have a brownish or fawn colour, somewhat like mahogany wood, with a smooth, though sometimes finely tuberculated surface, they almost always consist of lithic acid. When cut open they appear to be formed of concentric layers, sometimes homogeneous, sometimes alternating with other substances. The colour, however, cannot be considered as a certain criterion, since other kinds of calculi may often be coloured in the bladder, in a similar manner, by bloody mucus, or other vitiated secretions.

When calculi are white, or grayish-white, they always consist of earthy phosphates. This is particularly the case with the species called fusible. And when they are dark brown, or almost black, hard in their texture, and covered with tubercles or protuberances, they are generally of the species which has been distinguished by the name of *mulberry*, and consist of oxalate of lime.

Calculi have sometimes an uneven, crystalline surface, studded with shining, transparent particles. This appearance always denotes the presence of the ammoniaco-magnesian phosphate."—(*Marcet*, *p.* 52.)

A large calculus, especially when it has a rough, irregular surface, produces a great deal of irritation of the bladder, which contracts more closely round it. The contact, however, is remarked to be particularly exact at the transverse line, which extends between the terminations of the two ureters in the bladder; a part of this organ which generally becomes more thickened than the rest. Sometimes, indeed, the cavity of the bladder is nearly effaced, and the urine can be retained only a very short time, or, if it be not evacuated, it spreads uniformly round the calculus, especially above and below the above-described transverse projection, which is less yielding than other parts of this organ. Hence, the surface of the stone, towards the orifices of the ureters, does not enlarge so fast as the other sides of it, and a circular groove is produced, giving the foreign body the shape of a calabash. Such calculi are generally very large, and sometimes even of enormous size. In the latter circumstance, the foreign body fills the cavity of the bladder so completely, that there is no space left for the lodgement of the urine there, which fluid then generally passes along a sort of groove, situated in a line reaching from the lower termination of the ureter to the neck of the bladder. This state is of course accompanied with a complete incontinence.

Urinary calculi are not always loose and moveable in the cavity of the bladder; being sometimes fixed in various ways to certain points of the circumference of this organ; a subject which has been noticed in the article *Lithotomy*.

When the bladder protrudes from the abdomen so as to form a hernia, a stone is occasionally situated in the displaced portion of it. This circumstance has the same effect as the encysted state of a calculus; for the foreign body is thereby fixed, and it cannot be propelled towards the neck of the bladder at the period when the urine is discharged. Also, in cases of prolapsus uteri, when the bladder is drawn downwards, a stone has sometimes been found lodged at the lowest part of it. The possibility of the complication of a calculus with such displacements of the bladder, ought to be well remembered, since, if the nature of the case be detected, its treatment becomes materially simplified.

The symptoms of a stone in the bladder have been detailed in the article *Lithotomy*, and therefore need not here be repeated. They are all so equivocal, and bear so great a resemblance to the effects of several other disorders, that they cannot be depended upon, and consequently no well-informed surgeon will venture to pronounce positively that there is a calculus in the bladder, unless he can distinctly feel it with a sound.—(See *Lithotomy* and *Sounding*.) As for the operation, if the surgeon cannot plainly feel the calculus immediately before he commences the incisions, it ought to be postponed.

Notwithstanding the laudable zeal with which various distinguished physicians and surgeons of the present day have applied themselves to the consideration of the causes of urinary calculi, the subject is yet in great obscurity. The conjectures which have been started, respecting the influence of particular kinds of food, drink, air, and habits of life, are all of them liable to such objections as throw considerable doubts on their correctness, and sometimes amount to a decided refutation of them.

If a foreign body be introduced into a cavity to which the urine has access, whatever may be the nature of the immersed substance, it always becomes after a time incrusted with calculous matter, though it undergoes no chemical change in its composition. In such cases, it is found (see *Forbes on Gravel and Gout*, *8vo. Lond.* 1793; and *Marcet on the Chemical Hist., &c. of Calculous Disorders*, *8vo. Lond.* 1817) that the concretion mostly, if not always, consists of the earthy phosphates. Here the operation of any particular diathesis is beyond all suspicion, because the foreign body which forms the nucleus would lead to the production of a calculus in all descriptions of patients.

There are some countries, where patients with calculi are tolerably numerous; and other parts of the world, where the disease is rare, or never met with; and yet the difference cannot always be accounted for by any geographical circumstance, which is constant, or any definable peculiarity of constitution, climate, diet, or mode of life. One fact, however, I believe, is certain, viz. the uniform rarity of the disease in *very hot* countries. In tropical climates, urinary calculi are almost unknown, and, as Dr. Marcet observes, the testimony of Dr. Scott on this point, who long resided in India, must be considered valuable. Dr. Scott affirms, that, between the tropics, he never met with a single instance of the formation of a stone in the urinary bladder, although he knew of some cases which had been imported and were not cured by climate.—(See *Marcet on the Chemical History and Med. Treatment*

of Calculous Disorders, chap. 2, 8vo. Lond. 1817.) Yet, as calculi frequently form on various nuclei, bullets, pieces of bougies, &c., I conceive, that even in India, calculi will some day or another be found to originate from this cause, though not perhaps from diathesis.

Urinary calculi are said also to be very uncommon in Spain and Africa, though patients with gravel are numerous in Majorca, which lies between them.—(*Magendie, Recherches sur les Causes, &c. de la Gravelle, p.* 31, *8vo. Paris*, 1818.) The usual belief is, that calculi are most frequent in damp, cold countries, like England and Holland, but that in such other parts of the world as are either very hot or cold, the disease is rare. However, in every estimate of this kind, the number of the inhabitants of the countries or districts in question, is always an essential thing for consideration, because the proportion of stone-patients, in a given number of individuals, is invariably rather small; and, therefore, in referring to the rarity of such patients in very cold countries, it is to be considered, whether the fact may not be, in some measure, ascribable to the fewness of the inhabitants. The state of medicine and surgery, in the countries from which the information is transmitted, is likewise another thing for contemplation, inasmuch as patients are not likely to be reported as suffering from or dying of stone, where the nature of diseases is not scientifically observed, morbid anatomy is uncultivated, and the operation of sounding never attempted. However, as our East India native regiments are furnished with excellent surgeons, I consider it well proved, that in those regiments the disease is uncommon, for otherwise the statement would no doubt have been contradicted by them. The fact seems, therefore, well established, in relation to the East Indies. At the same time, the ages of the individuals to whom any calculation applies, is always to be taken into consideration before any inference be drawn respecting the cause of the rarity of calculi; because, if the disease be rare among soldiers in India, it is also rare among soldiers in Europe, and therefore climate would not explain the fact in both parts of the world. But, probably, the recollection that common soldiers are neither children, nor men above the middle period of life, and that the first formation of stone in youths, adults, and middle aged persons, is uncommon, unless some extraneous substance happen to enter the bladder and form the nucleus, may furnish a reason for the infrequency of the disease among soldiers, applicable perhaps to such individuals in every country. And that the children of soldiers, like those of other persons, are not exempt from the disease, I know very well, having had occasion myself to operate upon a patient of this kind during my service with the army.

The preceding consideration also of the general age of sailors in the royal navy, and of the little chance there must be of a boy with stone, being sent to sea, or of any sailor being admitted on board of a king's ship with that disorder, unless it be wilfully concealed by the man himself, furnish to my mind a better explanation of the cause of so few cases of stone having been met with among seafaring persons, than any of the references to the habits or mode of life of a sailor made by Mr. C. Hutchison in his ingenious paper.—(See *Med. Chir. Trans. vol.* 9, *p.* 443, *&c.*) From this gentleman's account it seems, that out of 86,000 patients admitted into the naval hospitals at Haslar, Plymouth, and Deal, in the space of sixteen years, there have only been eight calculous cases, or one in 10,750 patients. *Two of these cases were boys, about fourteen years of age, "who had laboured under symptoms of stone for some years previously to their admission into the service, and into which they had recently entered expressly for the purpose of deriving benefit from our magnificent institutions;* one was a marine who had been at sea a few months only; three were adult seamen, and the seventh a marine; *but their length of service afloat could not be at all ascertained:* the eighth and last case was a warrant-officer, *advanced in years*, who had been serving in ordinary, that is, in a ship in harbour, for a considerable time previously to the operation." Subsequently to the period embraced by the returns, collected by Mr. C. Hutchison, *a boy* has also been operated upon in Haslar Hospital.—(*Vol. cit. p.* 449.) Mr. R. Smith, of Bristol, has published an interesting statistical inquiry into the frequency of stone in the bladder, in Great Britain and Ireland, though strictly it is a comparative estimate of the number of operations for stone in different parts of the kingdom in given spaces of time, and not of the number of calculous patients.—(See *Med. Chir. Trans. vol.* 11.) As far as I can judge from the facts stated in Mr. Smith's paper, and from what I know about the average number of operations for stone in London, not more than 180 can be fairly reckoned as the annual total in Great Britain and Ireland, which is about 1 for each 100,000 of the population, taken at 18,000,000. Now, if this fact be recollected, in computing the rarity of stone-operations in the navy, and the other circumstances of there being few children and old men in that service, and of every man being examined by a surgeon, as to the state of his health, before he is entered, I think the reason of the infrequency of stone in the navy will be tolerably clear. However, as sailors live partly in very hot and partly in very cold climates, even if they were of the ages most subject to calculi, they may perhaps be rather less disposed to the complaint than individuals of the same periods of life constantly resident in England. In the cold country of Sweden, urinary calculi are said to be unfrequent (*Richerand, Nosogr. Chir. t.* 3, *p.* 528, *ed.* 4); and as surgery is there highly cultivated, the uncontradicted statement weighs considerably in favour of the truth of the general belief in the rarity of this disorder in very cold countries. But as I have already said, the number of inhabitants to which any particular evidence on this point relates, is an essential inquiry, before a safe inference can be drawn.

It is perfectly well ascertained, that the greater number of urinary calculi are composed chiefly of lithic or uric acid, which is naturally contained either in a free or combined state in the urine of man, and all other animals which consume a great deal of food abounding in azote, as flesh of every kind, fish, shell-fish, eggs, &c. Whenever the urine will redden the tincture of turnsol, Magendie infers, with the generality of chemists, that it contains lithic acid, the proportion of which, he says, varies according to the quantity of substances abounding in azote taken as food. And Magendie farther observes, that when animals live altogether on flesh, their urine is full of uric acid, and even may be entirely composed of it, as is proved with respect to birds, by the experiments both of Dr. Wollaston and Vauquelin. Here Magendie cannot mean free uric acid, but this acid in a state of combination; for, as Dr. Prout has observed, there is no instance known in which lithic or uric acid is secreted in a pure state; birds, serpents, &c. always secrete it in combination with ammonia; in the gouty chalk-stone it is secreted in combination with soda.—(*On the Nature, &c. of Gravel and Calculus, p.* 13.) On the contrary, if animals live on vegetables, as is the case with the herbivorous class, Magendie states, that there is no appearance of lithic acid in their urine. In a series of experiments, communicated by Magendie to the Academy of Sciences in 1816, this distinguished physiologist exemplified, that if a carnivorous animal be deprived of all nutriment containing azote, and be fed with sugar, gum, oil, and other substances considered to be nutritious, and having no azote in their composition, the urine, in three or four weeks, will contain no lithic acid.—(See *Mém. sur les Propriétés nutritives des Substances, qui ne contiennent pas d'azote. Paris*, 1817.) A dog, allowed only sugar and distilled water, soon began to grow lean and died apparently starved on the 32d day from the commencement of his diet. The inference which Magendie draws from his experiments, and from some cases which he has detailed, is, that the quantity of uric acid in the urine, and, of course, the tendency to gravel and calculous disorders, depend very much upon the kind of food. However, he takes into consideration the relative proportion of the uric acid to the urine itself; because, if this be also abundant, the liability to calculi is counteracted. It would appear also, from his observations, that the urine not only becomes impregnated with a great proportion of uric acid in animals which eat a large quantity of flesh, but is also scanty; and that, on the other hand, a vegetable diet always promotes the secretion of a large quantity of fluid from the kidneys, as well as checks the formation of the acid in question. Magendie is also disposed to believe, that the rarity of calculi in hot climates may be partly traced to the kind of food

employed. In fact, it is well known, that in a considerable part of Asia many millions of the inhabitants never eat flesh. But though this circumstance must be allowed to have full weight with respect to the sects which religiously decline animal food, the influence of climate cannot be rejected, because calculi are rare in all hot countries, whether meat be freely eaten or not. At the same time, the tenor of this gentleman's reasoning may be true, that, setting out of the question the influence of climate, a vegetable diet tends to prevent the formation of lithic acid calculi, while eating large quantities of such food as contains a great deal of azote has the opposite effect.

However, Magendie himself is not so partial to his theory, as not to confess that it is liable to objections; for, says he, individuals are met with every day, who, from their age, manner of living, and habits, appear to be subjected to every condition calculated to produce the gravel, and yet they remain free from it. Hence he infers that there must be some unknown causes which sometimes keep the uric acid dissolved, even where its quantity in the urine is copious. On the other hand, he admits that certain persons are met with, whose regimen and mode of life ought to exempt them from gravel, and still they are afflicted. In proof of this fact, he adverts to the poor inhabitants of a district in Sussex, mentioned by Dr. Scudamore (*On the Nature and Cure of Gout, &c.* 8vo. *Lond.* 1817), who live almost entirely on vegetable matter and hard beer, and many of whom are much troubled with gravel. Magendie might also have recollected, that some birds, which live entirely on vegetable matter, as several singing-birds kept in cages, void a good deal of the lithate of ammonia. Magendie refers to examples of gravel being always produced in certain individuals after any unusual exertion, and in other apparently healthy subjects, after any difficulty of digestion, flatulence, the eating of salad, raw fruit, &c. With regard to the dyspepsia, frequently attendant on calculous disorders and other chronic diseases, Magendie sets down the complaints of the stomach and of the urinary organs, as probably only two effects of the same cause, and not mutually productive of each other.—(See *Recherches, &c. sur les Causes, &c. de la Gravelle*, 8vo. *Paris*, 1818.)

It should be observed, that Magendie's observations are meant to apply only to cases of gravel, and where the substance voided is lithic acid. And as for other instances in which the calculous matter is formed of phosphate of lime, oxalate of lime, cystic oxyde, &c. he deems the causes entirely unknown. One thing is certain, that Magendie's theory will not account for the origin of calculi, unless a predisposition to the disease from other unknown or conjectured causes, be taken as a matter of fact. Indeed, this admission he makes himself; and he enumerates various circumstances conducive to gravel, besides a diet of food abounding in azote; as advanced age; a sedentary life, and hard study; long retention of the urine in the bladder; strong wines and liquors. In fact, without the predisposition arising from unknown causes and particular periods of life, a meat diet will not render the occurrence of calculi frequent, as is exemplified in sailors who eat a great deal of salt beef and pork. And, on the contrary, that the eating of little or no animal food will not always prevent the formation of calculi, when there is tendency to it from time of life, diathesis, or other causes, is sufficiently proved by the frequency of the disease in infants, in whose food there is a much smaller proportion of meat and azotic substances than in the usual diet of an adult.

With respect to *amorphous sediments*, the circumstances which Dr. Prout has observed to produce a lithic acid diathesis in persons subject to slight dyspepsia, but in other respects healthy, are, 1. Simple errors in diet; 2. Unusual or unnatural exercise, either bodily or mental, particularly after eating, and the want of proper exercise at all other times; 3. Debilitating circumstances.—(*On Gravel, Calculus, &c. p.* 113.) An unusually heavy meal, especially of animal food, or bread, he says, is *invariably* followed by a deposition of the lithate of ammonia from the urine. Heavy unfermented bread, and compact, hard-boiled, fat dumplings or puddings, he finds particularly apt to produce such an effect.

Crystallized sediments or *gravel*, consisting of nearly pure lithic acid, Dr. Prout ascribes to a free acid being sometimes generated in the kidneys, and, combining with the ammonia with which the lithic acid is previously united, so as to precipitate the latter in a pure crystallized state. According to the investigations of Dr. Prout, the precipitating acid is not constantly the same, though generally the phosphoric, and sometimes the sulphuric.—(*P.* 127, 128.)

The same intelligent writer represents the circumstances which promote the formation of urinary sediments in general, as being either *natural* or *acquired*. "With respect to those of the first description (says he), it cannot, I think, be doubted, that certain individuals are much more liable to these sediments than others. This tendency is not unfrequently inherited: thus, I know a family, where the grandfather and father have actually lithic calculi in the bladder; and where the grandson, a youth of twelve or thirteen years of age, has a very strong tendency to the same disease; his urine depositing frequently very large quantities of lithic acid, both in the form of amorphous and crystalline sediments. On the other hand, the disposition to generate these sediments in excess is, like gout, or rather simultaneously with gout, but too frequently acquired by indolent habits, and excess in eating and drinking. Most frequently, however, the tendency to these diseases is connected with some unknown causes, peculiar to certain districts or countries; as, for example, the district of which Norwich may be considered the centre; in which more calculous cases occur than in the whole of Ireland or Scotland. In such instances, the water, diet, temperature, &c. of the district, has been each accused in its turn, of being the exciting cause; but (says Dr. Prout), the circumstance, I believe, still remains unexplained. I have, in one or two instances, seen a fit of lithic gravel induced in the predisposed by sitting on a damp, cold seat for some hours. Sometimes also a tendency to lithic calculus is evidently connected with local injury, or disease of the kidney."—(*P.* 133.)

The difficulty of tracing the causes of the formation of calculi, is rather increased than lessened by the fact, that except when the urinary organs are much diseased, the patient may appear to be in perfect health. Indeed, persons of the strongest constitutions are often troubled with the stone, quite independently of the entrance of any foreign body, as a nucleus, into the bladder; and it is now universally admitted, that lithic acid itself constitutes by far the most common nucleus, even when other calculous matter is deposited round it.—(See *Prout on Gravel, p.* 95.) It is sometimes conjectured that the female is less liable than the male sex to calculi; but whether this is the fact, or whether the circumstance can be satisfactorily explained on another principle, viz. the facility with which any calculi of moderate size are generally discharged through the short and capacious meatus urinarius, are questions perhaps not yet completely settled.

Infants and children to the age of twelve or fourteen are very liable to stone. However, it is asserted by Delpech, that at this period of life relapses are unfrequent; that is to say, an entirely fresh stone is hardly ever formed again; and, if a return of the complaint happens, the quickness of its recurrence, and an attentive examination of the calculus, will mostly prove, either that the second stone has formed round a fragment of the first left behind, or that it existed when the former one was taken out, but was not discovered. I am not inclined myself to put much faith in this statement, because it is hardly credible that the calculous diathesis of childhood can be at all diminished by the circumstance of there having already been one calculus, and of the patient having had the bladder opened for its removal.

Dr. Marcet thinks that the disorder is frequent only among the children of the poor classes; and that in those of the higher ranks, or even of the lowest classes, *provided they are well fed*, the same frequency is not observed. "In the Foundling Hospital, for instance, within the last 27 years, during which 1151 children have been admitted, only three cases of stone have occurred, all of which were among children while at nurse in the country. And, in the Military Asylum at Chelsea, which contains about 1250 children, and into which upwards of 6000 of them have been already admitted, no more than one single case of stone has occurred."—(See *Marcet's Essay on Calculous Dis-*

orders, p. 36.) However, supposing that the foregoing statement refers to operations for stone, and that the average number of operations for the population of Great Britain and Ireland, is annually about one for each 100,000 inhabitants, the inference drawn by Dr. Marcet, which also does not agree with later statistical reports, cannot be received, because, in the total number of children specified as having been admitted into the above charities, even when every allowance is made for the time comprised in the calculation, the proportion of operations is far beyond the average, with reference to the population in general. And that stone cases are more numerous in the children of the poor than in those of the higher classes, is a fact which perhaps may be explained by the recollection that the mass of the population consists of the poor and laborious classes.

In the period of life between the age of twelve or fourteen, and that of forty, the liability to stone in the bladder is much less than in infancy, childhood, or old age. And, no doubt, many of the cases which do present themselves in adults or middle-aged individuals, either began at an earlier period of life, or are owing to some extraneous nucleus.

According to Delpech, in old men who are particularly subject to calculi, the disposition to the return of the disease always continues during life; and hence in them relapses are frequent.—(*Précis des Mal. Chir. t.* 2, *p.* 193, *&c.*)

The following table, collected by Dr. Prout, exhibits the proportion of stone cases before and after puberty, and of their occurrence in the different sexes:

	Bristol.	Leeds.	Norwich.	Total.	Consisting of Males.	Consisting of Females.
14 years and under,	178	96	235	509		
Above 14 years,	177	101	271	549		
	355	197	506		1014	44

Thus, nearly one-half of the whole number of stone cases occur before the completion of the 14*th year*; and it appears also from Mr. Smith's valuable reports, that *there is an evident increase in the number of cases, about the age of forty years.*—(See *Prout on Gravel, &c. p.* 210; and *R. Smith, in Med. Chir. Trans. vol.* 10.)

Dr. Marcet has estimated the comparative frequency of the disease in various countries, and in the different stations of life, and tried to ascertain whether its frequency be influenced by varieties of climate, or situation, or by peculiarities in our habits and occupations. He instituted inquiries at all the great hospitals of the metropolis, in the hope of getting at some useful records concerning the vast number of patients on whom lithotomy had been performed in those establishments. In London, he found it impossible to obtain all the particulars of such cases, as no entry of them had been preserved. The Norwich Hospital, however, afforded him some details which are interesting. All the calculi which have been extracted in that hospital for 44 years, viz. from 1772 to 1816, and which amount to 506, have been carefully preserved, with the circumstances annexed to each stone, and the event of the operation distinctly recorded. Dr. Marcet has given the results of these records in the following table:

	Number of Operations.			Deaths.		
	Children under 14.	Adults.	Total.	Children	Adults.	Total.
Males,	227	251	478	12	56	68
Females,	8	20	28	1	1	2
	235	271	506	13	57	70

It appears, says Dr. Marcet, from the above table, that the mean annual number of cases of lithotomy in the Norwich Hospital during 44 years, has been 11½, or 23 in every two years; and that the total number of fatal cases in the 506 operations, is 70, or 1 in 7¼, or 4 in 29. The proportion of females who have undergone the operation is to that of males as 58 to 1000, or about 1 to 17; that the mortality from the operation in children was only about 1 in 18, while in adults it was 4 in 19, or nearly quadruple.

According to Mr. Smith, the mortality from lithotomy at the Bristol Infirmary, has been in the following proportions:

Age.	Rate of Mortality.
10 years of age and under,	1 in 4½
Between 10 and 20 ——	1 5
20 —— 30 ——	1 7
30 —— 40 ——	1 5
40 —— 50 ——	1 3½
50 —— 60 ——	1 4⅔
60 —— 70 ——	1 2½
70 —— 80 ——	1 2
Mean at all ages,	1 in 4¼

	Cases of Lithotomy.	died, of which	or 1 in	
From 1767 to 1777	24,	2	1 in 12	
1777 1787	62	8	1	7¾
1787 1797	23	3	1	7⅔
1797 1807	42	7	1	6
1807 1817	46	8	1	5¾
Mean at all ages,			1 in 7 4-5	

The preceding table is also from Mr. Smith's paper, and refers to the Leeds Hospital.—(See *Med. Chir. Trans. vol.* 10.)
